Multidimensional scaling’s map (or spatial representation) of a set of n objects consists of a set of n m -dimensional coordinates, each one of which represents one of the n objects. The required coordinates are generally found by minimizing some measure of goodness-of-fit between the inter-point distances implied by the coordinates and the observed (dis)similarities. MDS seeks to find the best-fitting set of coordinates and the appropriate value of the number of dimensions m needed to adequately represent the observed (dis)similarities. The hope is that the number of dimensions, m , will be small, ideally two or three, so that the derived configuration of points can be easily plotted. It is important to note that the configuration of points produced by any MDS method is indeterminate with respect to translation, rotation, and reflection. There is no unique set of coordinate values that give rise to a set of distances since the distances are unchanged by shifting the whole configuration of points

from one place to another or by a rotation or a reflection of the configuration. In other words, one cannot uniquely determine either the location or the orientation of the configuration of points.

There are mainly two types of MDS, depending on the scale of the (dis)similarity data: metric multidimensional scaling and non-metric multidimensional scaling. The metric multidimensional scaling is adequate when dissimilarities are also distances. In contrast, non-metric multidimensional scaling is appropriate when dissimilarities are not distances. The metric MDS uses the actual values of the dissimilarities, while the non-metric MDS effectively uses only the rank order (orderings) of the dissimilarities. These two types of MDS also differ in how the agreement between fitted inter-point distances and observed dissimilarities is assessed. A complete description of the theoretical and practical aspects of MDS can be found in the following reference books: Cox and Cox (2000), Borg and Groenen (2005), and Borg et al. (2018).

(Dis)Similarity Measure

Multidimensional scaling (MDS) is based on similarity or dissimilarity information between pairs of objects. The similarity between two objects is a numerical measure of the degree to which the two objects are alike. Thus, similarities are higher for pairs of objects that are more alike. In contrast, the dissimilarity between two objects is the numerical measure of the degree to which the two objects are different. Dissimilarity is lower for more similar pairs of objects. The term proximity is often used as an umbrella that encompasses both dissimilarity and similarity.

Let O be the set of objects. A similarity measure s on O is defined as $s: O \times O \rightarrow \mathbb{R}$ such that: (1) $s(\mathbf{x}, \mathbf{y}) \leq s_0$; (2) $s(\mathbf{x}, \mathbf{x}) = s_0$; and (3) $s(\mathbf{x}, \mathbf{y}) = s(\mathbf{y}, \mathbf{x})$; if in addition, (4) $s(\mathbf{x}, \mathbf{y})s(\mathbf{y}, \mathbf{z}) \leq [s(\mathbf{x}, \mathbf{y}) + s(\mathbf{y}, \mathbf{z})]s(\mathbf{x}, \mathbf{z})$ (triangle inequality), s is called a metric similarity measure.

A dissimilarity measure is a function $d: O \times O \rightarrow \mathbb{R}$ such that: (1) $d(\mathbf{x}, \mathbf{y}) \geq 0$; (2) $d(\mathbf{x}, \mathbf{x}) = 0$; and (3) $d(\mathbf{x}, \mathbf{y}) = d(\mathbf{y}, \mathbf{x})$; if in addition, (4) $d(\mathbf{x}, \mathbf{z}) \leq d(\mathbf{x}, \mathbf{y}) + d(\mathbf{y}, \mathbf{z})$ (triangle inequality), d is called a metric dissimilarity measure (distance measure).

A (dis)similarity matrix is a matrix such that their elements (representing (dis)similarities between pairs of objects) fulfill the conditions depicted above. The input data for MDS is in the form of a dissimilarity matrix representing the dissimilarities between pairs of objects. When the similarities are available, MDS requires first to convert the similarities into dissimilarities. There are many ways of transforming similarity measures into dissimilarity measures. One way is to take $d(\mathbf{x}, \mathbf{y}) = s_0 - s(\mathbf{x}, \mathbf{y})$, $\forall (\mathbf{x}, \mathbf{y}) \in O \times O$.

Metric MDS

Assume that there are n objects with dissimilarities δ_{ij} between them, for $i, j = 1, \dots, n$ (one dissimilarity for each pair of objects). Let $\mathbf{\Delta} = [\delta_{ij}]$ be the $n \times n$ dissimilarity matrix. The metric MDS attempts to find the coordinates of the n objects in a m -dimensional Euclidean space, in the form of an $n \times m$ matrix of coordinates values $\mathbf{X} = [\mathbf{x}_{kl}]$, where each point represents one of the objects, and the inter-point distances $d_{ij}(\mathbf{X})$ are such that:

$$d_{ij}(\mathbf{X}) \approx f(\delta_{ij}), \quad (1)$$

where $f(\cdot)$ is a continuous parametric monotonic function, such that $f(\delta_{ij}) = \alpha + \beta\delta_{ij}$. The function $f(\cdot)$ can either be the identity function or a function that attempts to transform the dissimilarities to a distance-like form. The two main metric MDS methods are classical scaling and least squares scaling.

Classical Scaling

Classical scaling transforms a dissimilarity matrix into a set of coordinates such that the (Euclidean) distances derived from these coordinates approximate as closely as possible the original dissimilarities. The basic idea of classical scaling is to transform the dissimilarity matrix into a cross-product matrix and then perform its spectral decomposition, which gives a principal component analysis (PCA). Given the dissimilarity matrix $\mathbf{\Delta} = [\delta_{ij}]$, the classical MDS carried out the following steps:

1. Construct the matrix $\mathbf{A} = \left[-\frac{1}{2}\delta_{ij}^2\right]$.
2. Form the matrix $\mathbf{B} = \mathbf{H}\mathbf{A}\mathbf{H}$, where $\mathbf{H} = \mathbf{I} - n^{-1}\mathbf{1}\mathbf{1}^T$ is the centering matrix of size n and $\mathbf{1}$ is a column-vector of n ones.
3. Perform the eigen-decomposition of $\mathbf{B} = \mathbf{\Gamma}\mathbf{\Lambda}\mathbf{\Gamma}^T$, where $\mathbf{\Lambda} = \text{diag}(\lambda_1, \dots, \lambda_n)$ is the diagonal matrix formed from the eigenvalues of $\mathbf{B}$, and $\mathbf{\Gamma} = [\mathbf{\Gamma}_1, \dots, \mathbf{\Gamma}_n]$ is the corresponding matrix of eigenvectors; the eigenvalues are assumed to be labeled such that $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n$.
4. Take the first m eigenvalues greater than 0 ($\mathbf{\Lambda}_+$) and the corresponding first m columns of $\mathbf{\Gamma}$ ($\mathbf{\Gamma}_+$). The solution of classical MDS is $\mathbf{X} = \mathbf{\Gamma}_+\mathbf{\Lambda}_+^{1/2}$.

If the dissimilarity matrix $\mathbf{\Delta}$ is Euclidean, i.e., the matrix $\mathbf{B}$ is positive semi-definite, an exact representation of dissimilarities, that is, one for which $d_{ij} = \delta_{ij}$, can be found in a q -dimensional Euclidean space. The coordinate matrix of classical MDS is then given by $\mathbf{X} = \mathbf{\Gamma}_q\mathbf{\Lambda}_q^{1/2}$, where $\mathbf{\Lambda}_q$ is

the matrix of the q non-zero eigenvalues and Γ_q is the matrix of the corresponding q eigenvectors. Using all q -dimensions will lead to complete recovery of the original Euclidean dissimilarity matrix. The best-fitting m -dimensional representation is given by the m eigenvectors of $\mathbf{B}$ corresponding to the m largest eigenvalues. The adequacy of the m -dimensional representation can be judged based on one of the following two criteria:

$$P_m^{(1)} = \frac{\sum_{i=1}^m |\lambda_i|}{\sum_{i=1}^n |\lambda_i|}, \quad P_m^{(2)} = \frac{\sum_{i=1}^m \lambda_i^2}{\sum_{i=1}^n \lambda_i^2}. \quad (2)$$

It is important to highlight that when the dissimilarity matrix contains Euclidean distances calculated from an $n \times q$ data matrix $\mathbf{X}$, classical scaling can be shown to be equivalent to principal component analysis (PCA), with the required coordinate values corresponding to the scores on the principal component extracted from the covariance matrix of the data. One result of this duality is that classical multidimensional scaling is also referred to as principal coordinates analysis (PCoA). Classical scaling can also be formulated in terms of the optimization of a particular goodness-of-fit function. The classical scaling solution is optimal in the least squares sense. The m -dimensional principal components solution ($m < q$) is “best” in the sense that it minimizes the following goodness-of-fit:

$$\text{Strain}(\mathbf{X}) = \left(\sum_{i,j} (d_{ij}(\mathbf{X}) - \delta_{ij})^2 / \sum_{i,j} d_{ij}^2(\mathbf{X}) \right)^{1/2} \quad (3)$$

where δ_{ij} is the Euclidean distance between objects i and j based on their original q variable values and $d_{ij}(\mathbf{X})$ is the corresponding distance calculated from the m principal component scores.

If the dissimilarity matrix Δ is not Euclidean, the matrix $\mathbf{B}$ is not positive semi-definite. In this circumstance, some of the eigenvalues of $\mathbf{B}$ are negative; correspondingly, some coordinate values are complex. If, however, $\mathbf{B}$ has only a small number of small negative eigenvalues, a useful representation of the dissimilarity matrix may still be possible using the eigenvectors associated with the m largest positive eigenvalues. If, however, the matrix $\mathbf{B}$ has a considerable number of large negative eigenvalues, classical scaling may be inadvisable, and some other methods of scaling, for example, non-metric scaling, might be used instead.

Least Squares Scaling

Metric least squares scaling finds a configuration of points matching the inter-point distances $d_{ij}(\mathbf{X})$ to observed

dissimilarities δ_{ij} by minimizing a loss function, with possibly a continuous monotonic transformation of the dissimilarities, $f(\delta_{ij})$. To assess the match between inter-point distances and dissimilarities, one needs to define an objective function which takes the value zero if the inter-point distances and dissimilarities are a perfect match and increases in value as the fit becomes less good. An obvious candidate for such a function is a least squares type fit criterion, for instance:

$$\text{Stress}(\mathbf{X}) = \left(\sum_{i < j} (d_{ij}(\mathbf{X}) - f(\delta_{ij}))^2 / \sum_{i < j} d_{ij}^2(\mathbf{X}) \right)^{1/2} \quad (4)$$

The denominator in Eq. (4) is a normalizing term making the goodness-of-fit criterion scale-free. This normalization has the advantage that it makes the goodness-of-fit criterion values do not depend on the size of the configuration of points. A configuration of points that minimizes the goodness-of-fit criterion might be found by an appropriate optimization technique such as the steepest descent approach or iterative majorization method. Unlike classical scaling, least squares scaling is an optimization process minimizing a loss function through iterative algorithms. As one can note, the classical scaling algorithm is algebraic (closed-form solution) and not iterative.

Non-metric MDS

It is often not the actual values of dissimilarities that are important or meaningful but their values in relation to the distances between other pairs of objects. In many situations, the dissimilarities may contain little reliable information beyond that implied by their rank order. In other words, the dissimilarities do not have strict numerical significance, only an ordinal significance. For example, in comparing a range of colors, one might be able to specify that one was brighter than another without being able to attach any value to the exact numerical significance between them. In such circumstances, the dissimilarities can be interpreted only in an ordinal sense, and metric MDS will no longer be appropriate.

Non-metric MDS assumes that only the ranks or orderings of the dissimilarities are known. Hence, this method produces a map that tries to reproduce these ranks and not the observed or actual dissimilarities. Thus, only the ordering of the dissimilarities is relevant to the method. Consequently, the technique is invariant under monotonic transformations of the dissimilarities.

Given the $(n \times n)$ dissimilarity matrix Δ , non-metric MDS seeks to find a configuration of points $\mathbf{X} = [\mathbf{x}_{ki}] \in \mathbb{R}^q$ in a q -dimensional space, such that the following relation is satisfied as much as possible:

$$d_{ij}(\mathbf{X}) \approx h(\delta_{ij}), \quad (5)$$

where $h(\cdot)$ is a monotonic function that preserves the rank order of the dissimilarities: $\delta_{ij} < \delta_{kl} \Leftrightarrow h(\delta_{ij}) \leq h(\delta_{kl})$. Unlike metric MDS, here $h(\cdot)$ is much general and is only implicitly defined.

Thus, one seeks a configuration of points in a given dimension space so that the rank order of the inter-point distances best agrees with the dissimilarities' rank order. The configuration of points is determined such that the inter-point distances minimize a loss function defined by:

$$\text{Stress}(\mathbf{X}) = \min_h \left[\frac{\sum_{i < j} [d_{ij}(\mathbf{X}) - h(\delta_{ij})]^2}{\sum_{i < j} d_{ij}^2(\mathbf{X})} \right]^{\frac{1}{2}}, \quad (6)$$

where the minimization is performed over all monotonic functions $h(\cdot)$. Here $h(\delta_{ij})$ represents the monotone least squares regression of the $\{d_{ij}(\mathbf{X})\}$ on the $\{\delta_{ij}\}$. $h(\delta_{ij})$ is called disparities. Note that the original dissimilarities are only used in checking the monotonic condition. In fact, only the order $\delta_{ij} < \delta_{kl} < \dots < \delta_{mf}$ among dissimilarities is needed.

The loss function defined in Eq. (6) provides a measure of the degree to which the rank order of the configuration inter-point distances concurs with the rank order of the dissimilarities to be mapped. It is invariant by translation, rotation, or rescaling (uniform stretching or shrinking) of the configuration. So the non-metric MDS solution is only known up to one of these transformations. The loss function is minimized with respect to $d_{ij}(\mathbf{X})$, i.e., with respect to $\mathbf{X} = [\mathbf{x}_{kl}]$, the coordinates of the configuration, and also with respect to $h(\cdot)$ using isotonic regression.

The minimization of the loss function is performed using the Shepard-Kruskal iterative algorithm as described, for example, in Borg and Groenen (2005). It is a two-phase optimization algorithm. In each phase, one set of parameters (distances or disparities, respectively) is taken as fixed values, while the other set of arguments is modified in such a way that *stress* is reduced. One starts from an initial configuration $\mathbf{X}^{(0)}$. Then, one seeks $h(\delta_{ij})$ such that $\sum_{i < j} [d_{ij}(\mathbf{X}^{(0)}) - h(\delta_{ij})]^2$ is minimum. This problem admits a unique solution: isotonic regression. The value of the *stress* is thus deduced. The configuration of points is then modified by means of small displacement of points using the steepest descent method to reduce the *stress*. Then, one goes back to the isotonic regression phase and so on until convergence is reached. The choice of the starting configuration is essential to finding the global rather than a local minimum. In practice, the solution of the metric MDS is taken as the starting configuration. There are several other methods for choosing a starting configuration – for example, generating n points according to a Poisson process in a region of $\mathbb{R}^q$.

Goodness-of-Fit and Number of Dimensions

There are several ways of assessing the goodness of an MDS solution. The quality of an MDS solution can be assessed informally by plotting the original dissimilarities versus the corresponding inter-point distances in MDS space. This plot is known as a Shepard diagram. This latter shows how well inter-point distances within the configuration of points agree with the original dissimilarities. In an ideal situation, the points fall on the bisecting line. The Shepard diagram is highly informative. It shows the number of points that have to be fitted, the optimal regression line, the size of the deviations, possible outliers, and systematic deviations from the requested regression line.

Different indices can measure the formal goodness of an MDS solution. These indices measure how well the obtained configuration of points represents the set of pairwise dissimilarities. The common way to do this is by computing the MDS solution's goodness-of-fit criterion, such as the *stress*. This latter is a loss function: it is zero when the solution is perfect; otherwise, it is greater than zero. *Stress* aggregates into one measure the deviations of the points from the regression line in a data-versus-distances plot (Shepard diagram). A perfect MDS solution has *stress* = 0. If this is true, then the distances of the MDS configuration represent the data precisely (in the desired sense).

For each value of the number of dimensions, m , the configuration of points that has the smallest goodness-of-fit criterion is called the best-fitting configuration in m dimensions. A rule of thumb for judging the quality of an MDS solution has been provided by Kruskal based on his own experience with experimental and synthetic data: *stress* = 20% (poor), *stress* = 10% (fair), *stress* = 5% (good), *stress* = 2.5% (excellent), and *stress* = 0 (perfect). More recent articles caution against using a table like this since acceptable values of *stress* depends on the quality of the distance matrix and the number of objects in that matrix.

In the practical application of MDS, a critical question concerns the appropriate dimensionality of the resulting configuration of points needed to give an adequate representation of the observed dissimilarities. The goal is to keep the number of dimensions as small as possible, i.e., an MDS representation with considerably fewer dimensions. For illustrative or visualization purposes, the preferred number of dimensions to be chosen is two, at most, three dimensions. Using a two- or three-dimensional MDS solution makes more straightforward the interpretation of the results. Although a less well-fitted configuration in two dimensions may be preferable to one in several dimensions (where only projections of points can be graphically displayed), it is also essential to keep in mind that scaling with too few dimensions may distort the true MDS structure due to over-compression.

To choose an appropriate number of dimensions, it is advocated that several values of the number of dimensions are tried, and the goodness-of-fit criterion (such as the *stress*) of the final configuration of points is plotted against the number of dimensions. *Stress* always decreases as the number of dimensions increases; the greater the m , the smaller the expected *stress* (because higher-dimensional spaces offer more freedom for optimal positioning of points). What one looks at in this scree plot is an elbow in this curve, a point where the decrements in *stress* begin to be less pronounced, i.e., for which further increase in m does not significantly reduce *stress*. That point corresponds to the dimensionality that should be chosen. The rationale of this choice is that the elbow marks the point where MDS uses additional dimensions to essentially only scale the noise in the data after having succeeded in representing the systematic structure in the given dimensionality m .

Application Examples

Multidimensional scaling is used in geostatistics for many purposes. MDS is used to model non-stationary spatial dependence structure through the so-called space deformation approach (Fouedjio 2016; Fouedjio et al. 2015). The stationary assumption of the spatial dependence structure may not be suitable because the Euclidean distance is not an appropriate measure of the spatial separation. The spatial dependence structure can, for instance, follow geological patterns that lead to non-stationarity. However, using a distance other than the Euclidean distance in an isotropic stationary spatial dependence structure model may result in an invalid second-

order structure model. In this case, one can use the metric MDS method to embed locations of the study domain in a Euclidean space where the distances between points approximate well the original distances; thus, the validity of the second-order structure model is guaranteed (Boisvert and Deutsch 2011; Rivest and Marcotte 2012; Ver Hoef et al. 2006; Løland and Høst 2003). MDS is also used to analyze an ensemble of geostatistical simulations (de Barros and Deutsch 2017; Tan et al. 2014). This is useful for identifying redundant simulations and selecting a subset of representative simulations for an accurate and realistic risk assessment and decision analysis. It is also helpful for falsification of simulations, where one tests if simulations are consistent (in Bayesian sense) with the data (Fouedjio et al. 2021).

In the following, the application of MDS for visualizing an ensemble of geostatistical simulations is presented. Two examples considering continuous and categorical simulations are given. The first example considers 100 continuous geostatistical conditional realizations on 200×200 grid cells. The dissimilarity measure between two simulations (realizations) is defined as the square root sum of square differences between realizations, which is calculated cell-by-cell. So, the dissimilarity measure here is simply the Euclidean distance in the space spanned by the number of cells. The second example refers to 100 categorical geostatistical conditional realizations on 200×200 grid cells. There are four categories. The dissimilarity measure between two categorical simulations is defined using the Jaccard distance which is a distance measure dedicated to categorical data.

The classical metric MDS is applied to the resulting dissimilarity matrix in both examples. Figure 1 shows the

Multidimensional Scaling, Fig. 1 (a) (100×100) dissimilarity matrix (based on Euclidean distance) of an ensemble of 100 continuous geostatistical conditional realizations; (b) (100×100) dissimilarity

matrix (based on Jaccard distance) of an ensemble of 100 categorical geostatistical conditional realizations

Multidimensional Scaling, Fig. 2 Metric MDS representation of an ensemble of 100 continuous geostatistical conditional realizations; green dot represents the simulation #90; magenta dot represents the simulation

#77; red dot represents the simulation #20; blue dot represents the simulation #32; black dots represent the other simulations

dissimilarity matrix in the two examples. The 2D MDS representation of the ensemble of 100 continuous geostatistical conditional realizations is given in Fig. 2. Four simulations are also shown in the figure. Simulations #20 and #32 represent very close realizations; low and high values are well reproduced in both of the associated realizations. Simulations #77 and #90 represent realizations with large differences, which are reflected in their position in the MDS plot. Figure 3 depicts the 2D MDS representation of the ensemble of 100 categorical geostatistical conditional realizations as well as four realizations. Realizations #26 and #58 are very close in the MDS plot and show similar patterns. Realizations #74 and #98 have significant differences, which are reflected in their location in the MDS plot. In both examples, the classical metric MDS recreates the configuration of points in the $q = 99$ dimensional space that exactly matches the observed dissimilarities. Figure 4 presents the number of dimensions versus the goodness-of-fit criteria defined in Eq. (2).

Conclusion

Multidimensional scaling (MDS) represents (dis)similarities among objects by mapping points (representing the objects) into a multidimensional space in such a way that the inter-

point distances best agree with the (dis)similarities between the objects. Under MDS, one can visually inspect the (dis)similarities among the objects and investigate the principle underlying the organization of the (dis)similarities among these objects.

Although one can globally distinguish two types of MDS (metric multidimensional scaling and non-metric multidimensional scaling), there are various MDS models (or algorithms) depending on some factors such as the goodness-of-fit criterion used, the optimization method adopted, and the underlying transformation function chosen.

Like principal component analysis (PCA), MDS is also a dimension reduction technique because it aims to find a set of points in a low-dimensional space that approximate the possibly high-dimensional configuration represented by the original (dis)similarity matrix. However, MDS notably differs from PCA. Under the PCA, the data points were directly observable as n points in m dimensional space, but under MDS, one can only observe a function of the data points, namely, the dissimilarities. Like PCA, MDS can be used with supplementary or illustrative elements projected onto the dimensions after being computed. MDS is often combined with cluster analysis. Indeed, cluster analysis is performed on the low-dimensional representation of data resulting from MDS.

Multifractals

Renguang Zuo

State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan, China

Definition

Multifractal measures, or multifractals, proposed by Benoit Mandelbrot in 1972, are used to describe the phenomenon that the distribution of physical or other quantities is self-similar across many different scales in a geometric support (Feder 1988; Evertsz and Mandelbrot 1992; Cheng and Agterberg 1996). Multifractals are common in nature

including, for example, fully developed turbulence and distribution of gold across the Earth's surface (Halsey et al. 1986). Multifractals can be characterized by a continuous spectrum of fractal dimensions (Cheng and Agterberg 1996). Fractal is a mathematical concept that describes a pattern that repeats itself at many different scales (Mandelbrot 1967, 1977). Fractals are related to the notion of self-similarity, according to which the geometrical pattern on a specific length scale is the same as that on another length scale (Mandelbrot 1967). The fractal dimension (D) can be estimated from the negative slope of best fitting straight line on a log–log plot of number of objects versus the scale. The fractal dimension D is a positive real number, and reflects the complexity of the object.

Introduction

Multifractals have been shown to provide a useful mathematical concept in studies of the spatial distributions of physical and chemical quantities with geometrical supports. Many researchers have advocated the use of multifractals in the geosciences (e.g., Schertzer and Lovejoy 1991; Korvin 1992; Turcotte 1992; Agterberg 1994; Cheng et al. 1994; Cheng and Agterberg 1995, 1996). Multifractals have been successfully employed for characterizing both the frequency and spatial distributions of geological point processes, which occur widely in the geosciences, e.g., for mineral deposits, oil-producing wells, earthquakes, and landslides (e.g., Carlson 1991; Cheng and Agterberg 1995). At the same time, various multifractal models and related indices have been developed for measuring the complexity of geospatial patterns, such as maps of fractures (Agterberg et al. 1996) and geochemical elements (Xie and Bao 2004), and for separating geochemical anomalies from background in the context of mineral exploration (Cheng et al. 1994, 1999; Cheng 2007). The following sections introduce several multifractal models in the field of mathematical geoscience.

Multifractal Spectrum

The multifractal spectrum, a continuous function of singularity exponent α , is a commonly used tool to characterize multifractals. A monofractal corresponds to any single point in a multifractal spectrum, because it only has one singularity. Multifractal spectra are typically generated using one of three methods: the histogram method, the method of moments, or the direct determination method. The first two methods were introduced by Evertsz and Mandelbrot (1992), while the third method was proposed by Chhabra and Jensen (1989). In practice, the method of moments involving Legendre transformation is more widely used because it can yield better results than the other two methods (Agterberg 2014).

Meanwhile, the wavelet-based method (Arneodo et al. 1995) also can be used to construct a multifractal spectrum. For generating a multifractal spectrum for a geospatial pattern such as a geochemical map, let $\mu_i(\varepsilon)$ be the total metal amount of an element in the i th cell on a linear scale ε . The partition function $\chi_q(\varepsilon)$ then is given by (Evertsz and Mandelbrot 1992)

$$\chi_q(\varepsilon) = \sum_{N(\varepsilon)} \mu_i^q(\varepsilon), \quad (1)$$

where $N(\varepsilon)$ is the total number of cells with size ε . From a multifractal viewpoint, the relationship between $\chi_q(\varepsilon)$ and cell size ε can be modeled using a power-law statistic with $-\infty \leq q \leq +\infty$, i.e.,

$$\chi_q(\varepsilon) \propto \varepsilon^{\tau(q)}, \quad (2)$$

where $\propto$ represents proportionality, and $\tau(q)$ is the mass exponent of order q . The singularity exponent $\alpha(q)$ and the multifractal spectrum $f(\alpha)$ then can be obtained using the Legendre transformation (Evertsz and Mandelbrot 1992)

$$\alpha(q) = \frac{d\tau(q)}{dq}, \quad (3)$$

and

$$f[\alpha(q)] = \alpha(q)q - \tau(q), \quad (4)$$

Two indices (the multifractality and the asymmetry index) can be applied to quantify a multifractal spectrum. Cheng (1999) proposed an index based on the second derivative of the mass exponent function $\tau(q)$ at $q = 1$ to measure multifractality, i.e.,

$$\tau''(1) = \tau(2) - 2\tau(1) + \tau(0). \quad (5)$$

The multifractality provides a quantitative measure of irregularities (or regularities) in spatial distribution patterns. The higher the multifractality, the higher the degree of irregularity. The asymmetry index R (Xie and Bao 2004; Cheng 2014) is a measure of the symmetry of a multifractal spectrum:

$$R = \frac{\alpha(0) - \alpha_{\min}}{\alpha_{\max} - \alpha(0)}, \quad (6)$$

where $\alpha(0)$ is the value of α when $q = 0$, and $\alpha_{\min}$ and $\alpha_{\max}$ are the minimum and maximum values of α , respectively. $R > 1$ corresponds to a left-deviation multifractal spectrum with local enrichment; $R < 1$ corresponds to a right-deviation multifractal spectrum with local depletion; $R = 1$ suggests a symmetric multifractal spectrum.

Multifractal Inverse Distance Weighted Model

The multifractal inverse distance weighted model (MIDW) was developed by Cheng (2008). In the geosciences, sample point data are routinely interpolated into raster maps. The inverse distance weighted method (IDW), which is a frequently used interpolation method, assumes that the values of closer sample points contribute more to the interpolated values than the values of more distant sample points. The IDW method has the following disadvantages: (1) it does not consider the spatial variance in the values, and (2) it suffers from smoothing effects. The MIDW approach accounts for both the distance between neighboring points and the local structures and singularity of the field. It results in (Cheng 2008)

$$\rho(x_0, \varepsilon) = \left(\frac{\varepsilon}{\varepsilon_0}\right)^{\alpha(x_0)-E} \sum_{x_i \in \Omega(x_0, \varepsilon_{\max})} \lambda(\|x_i - x_0\|) Z(x_i), \quad (7)$$

where $\rho(x_0, \varepsilon)$ is the density function, $\alpha(x_0)$ is the singularity exponent at the location of x_0 , E is the Euclidian dimension of the pixel $\Omega(x, \varepsilon)$ (e.g., for a two-dimensional case, $E = 2$), ε is the pixel size, and $Z(x)$ is the value at point location x . In addition, $\lambda(\|x_i - x_0\|)$ is the weighting contribution of location x_i as a function of distance from x_i to x_0 , and $\sum \lambda(\|x_i - x_0\|) = 1$.

Number-Size Model

The number-size multifractal model (N-S), proposed by Mandelbrot (1982), is a basic fractal model for determining the relationship between the object size (S) and the number of objects (N) with sizes greater than or equal to a given size. The N-S model is parameterized as

$$N(\geq S) = cS^{-D}, \quad (8)$$

where c is a constant.

Concentration-Area Model

The concentration-area multifractal model (C-A) was proposed by Cheng et al. (1994). This model quantifies the relationship between the concentration and the area (A) where the concentration is greater than or equal to a given elemental concentration (ρ). This model has been used for identifying the threshold for separating geochemical anomalies from background. The C-A model is parameterized as

$$A(\geq \rho) = c\rho^{-D}, \quad (9)$$

On a log-log plot of $A(\rho)$ versus ρ , more than two straight lines can be fitted using the least squares method. The optimal

threshold for separating geochemical anomalies from background is the cutoff value of the fitted straight lines.

Spectrum–Area Model

The spectrum–area multifractal model (S–A) was developed by Cheng et al. (1999), for identifying geochemical anomalies in the frequency domain. The S–A model quantifies the power spectrum density (P) and area (A) with the power spectrum density above a given value, and is parameterized as

$$A(\geq P) = cP^{-D}. \quad (10)$$

The S–A model was developed based on the C–A model. The C–A model deals with data in the spatial domain, while the S–A model processes data in the frequency domain. Geospatial patterns can be converted into the frequency domain using Fourier transformation. A double logarithmic plot of P versus A with the spectral density above P can be constructed. M straight lines ($M \geq 2$) can be typically fitted, based on the S–A plot, using the least squares method. M straight lines define M filters for decomposing the original map into several components. Anomalous and background components can be obtained by converting each of these

components from the frequency domain into the spatial domain, using inverse Fourier transformation.

Local Singularity Analysis

Geological singular events, such as earthquakes and mineralization, typically lead to anomalous energy release and/or mass accumulation within a relatively narrow spatial-temporal interval (Cheng 2007). The energy release and/or mass accumulation patterns exhibit multifractal characteristics. Local singularity analysis (LSA) has been developed to quantify the multifractal distribution of geospatial patterns. For instance, when measuring the enrichment or depletion for a geochemical pattern, LSA yields the following power-law relation:

$$\mu(A) = cA^{\frac{\alpha}{2}}. \quad (11)$$

where $\mu(A)$ represents the total amount of metal within a region with area A , c is a constant, and α is the singularity exponent. The singularity exponent can be calculated using the ratio of the logarithmic transformation of measure μ and area A as follows:

Multifractals,

Fig. 1 Geochemical map of Zn in the Southwest Fujian Province of China

$$\alpha = \log\left(\frac{\mu_1}{\mu_2}\right) / \log\left(\frac{A_1}{A_2}\right)^{\frac{1}{2}}, \quad (12)$$

The sliding window technique can be used to estimate the local singularity exponent. For example, for a two-

dimensional (2D) geochemical map, let $A(r)$ be a set of square sliding windows centered at a certain location x , and let the size of each window be r , calculate the average concentration value $C[A(r_i)]$ for each window size r_i . On the log-log plot of $C[A(r_i)]$ versus r_i , a straight line can be fitted as

Multifractals,

Fig. 2 Multifractal spectrum of the geochemical pattern of Zn

Multifractals, Fig. 3 (a) Log-log plot of the cumulative area versus the concentration of Zn, and (b) the map of Zn anomalies identified using the C-A model

$$\log\{C[A(r)]\} = c + (\alpha - 2) \log(r). \quad (13)$$

The value of $\alpha-2$ can be estimated as the slope of the best-fitting straight line. For every location on a 2D field, $\alpha > 2$ suggests a depletion pattern, $\alpha < 2$ suggests an enriched pattern, and $\alpha = 2$ suggests a normal pattern. LSA can effectively detect weak anomalies in a complex geological setting (Cheng 2007).

Case Study

A geochemical map of Zn (Fig. 1) from the southwest Fujian Province of China was studied from a multifractal viewpoint in support of ArcFractal, which is an Add-in ArcGIS for processing geospatial data using fractal and multifractal models (Zuo and Wang 2020). The Zn data were collected from the Chinese National Geochemical Mapping Project

Multifractals, Fig. 4 (a) Log–log plot of the cumulative area versus the concentration spectrum density, and (b) anomaly and (c) background maps of Zn identified using the S–A model

(Xie et al. 1997). For this dataset, the density of the geochemical data points was about one sample per km^2 , out of which four samples were combined into one sample, capturing 4 km^2 . The raster map of Zn with a cell size of $1 \text{ km} \times 1 \text{ km}$ was created using the IDW method. Previous studies had suggested Zn was one of indicator elements for the presence of Fe-polymetallic mineralization in the study area (Zuo 2018). The multifractal spectrum of Zn is a continuous curve, not a single point (Fig. 2), indicating a multifractal distribution. Meanwhile, R is 3.65 (greater than 1.0), suggesting a left-deviation of the multifractal spectrum and a local enrichment pattern of Zn.

In the C–A plot, three straight lines could be fitted with different slopes (Fig. 3a). The right, middle, and left lines represent high anomalies, moderate anomalies, and background (Fig. 3b), respectively. Three straight lines also could be fitted in the S–A plot (Fig. 4a) representing noise, anomaly (Fig. 4b), and background (Fig. 4c) patterns of Zn, from left to right. The results of the S–A plot analysis show that the geochemical background of Zn (Fig. 4c) varies throughout the study area, meaning that different subareas have different background and anomaly values. These

observations suggest a complex geological setting of the study area. The anomalous patterns of Zn detected by the C–A, S–A, and LSA (Fig. 5) show close spatial correlations with the locations of known mineral deposits, indicating that these multifractal models can effectively identify geochemical anomalies on varied geochemical backgrounds linked to complex geological settings. It should also be noted that the S–A model suffers from edge effects (Ge et al. 2005), and several parameters (such as window shape and window size) affect the results of the LSA (Zuo et al. 2013).

Summary

Various geological processes or events exhibit complex and nonlinear characteristics, which can be modeled by using the concept of multifractals. Multifractals have gained significant attention in the field of mathematical geosciences, and have been used for processing geoscience data or exploring geological phenomena. This allows a full understanding of the origin, evolution, and future of Earth processes, with the aim of predicting and assessing its resources, environments, and

Multifractals, Fig. 5 Spatial distribution of the Zn singularity

natural hazards. Future studies should focus on obtaining insight into the mechanisms of geological processes and events from the multifractal viewpoint. Meanwhile, more case studies related to multifractal models are required for supporting mineral exploration, environmental assessment, and the effective prevention of natural disasters.

Multilayer Perceptrons

C. Özgen Karacan

U.S. Geological Survey, Geology, Energy and Minerals Science Center, Reston, VA, USA

Definition

Artificial neural networks (ANNs) are adaptable systems that can solve problems that are difficult to describe with a mathematical relationship. They seek relationships between different types of datasets with their abilities to learn either with supervision or without. ANNs recognize patterns between input and output space and generalize solutions, in a way simulating the human brain's learning experience with many relatively simple individual processing elements, called neurons. Neurons are networked (network topology) in a number of ways depending on the problem type and complexity. One of the most widely used ANN learning techniques is supervised learning coupled with a multilayer perceptron (MLP) topology due to its flexible applicability to a wide range of modeling problems involving both general classification and regression. ANNs, due to this flexibility, have been applied to many fields since the 1990s and their theory, types (such as radial basis functions, random forest, self-organizing maps,

and generalized feedforward network), and vast applications have been both documented in literature (e.g., Maier and Dandy 2000; Grima 2000; Karacan 2008, 2009; Rogerson 2019) and have been implemented in different software packages (e.g., Khan 2020).

Elements of an MLP Network

An MLP simulates a highly interconnected structure and parallel computing ability of a human brain. The input-output flow of the MLP is determined by the connections between neurons. The operation of a single neuron is dependent on the weighted sum of the incoming signals and a bias term, fed through an activation function, resulting in an output. For multiple neurons in a single-layer network topology, this process can be shown in mathematical terms as (Grima 2000):

$$y_i = f \left(\sum_{r=1}^n w_{ir} f \left(\sum_{j=1}^m v_{rj} u_j + b_r \right) + c_i \right) \quad i = 1, \dots, l \quad (1)$$

where u is the $m \times 1$ input vector, y is the $l \times 1$ output vector, n the number of neurons in the hidden layer, v and w are the

weight factors, $f(\cdot)$ is the activation function, and b_r and c_i are the bias values of the neurons in the hidden and output layers, respectively. Depending on the problem type and complexity, neurons are networked in a number of ways. Figure 1 shows a typical MLP structure with its parameters.

The simplest MLP structure has three layers: input layer, one hidden layer, and an output layer. Usually the number of neurons in the input layer is equal to the number of inputs, and the number of output neurons are equal to the desired number of outputs. For classification problems, number of outputs is at least two. One of the critical issues in developing MLP-type ANNs is the choice of the number of neurons, and thus weights, in the hidden layers. Both the number of hidden layers and the number of neurons in each of those layers may vary depending on the complexity of the problem, which should be optimized, for effective functioning and predictive capability (please see next section).

Within the layers, the inputs are summed and processed by a nonlinear function called a transfer function. There are different types transfer functions, but the “hyperbolic tangent” is generally the preferred type for function approximation problems. The nonlinear nature of this function plays an important role in the performance of the network. In the case of classification, the objective of the output layer is to bin the

Multilayer Perceptrons, Fig. 1 Structure and parameters of an MLP network that was developed and used to predict methane emissions from ventilation system of longwall mines. (Modified from Karacan 2008)

information propagating from the hidden layers into classes with either higher probability or lower probability. The transfer function of choice in classification problems is the “softmax” function in the output layer. This function scales the outputs between 0 and 1 so that the higher probability class will have a higher value compared to others.

Learning and Parameter Optimization

The predictive capability of a network is determined by optimizing the weights between the connections in hidden layers, and input and output layers. The process of finding a suitable set of weights is called “training.” Since the weights and the network characteristics are used in making predictions, it is one of the most important steps in the development of the MLP. The most common way of training is using supervised training algorithms with gradient descent, which requires repeated feed (epochs) of both input vectors and the expected outputs of the training dataset to the network. During each epoch, an error of prediction is calculated for a given pattern (input-output) and summed for all output neurons to calculate an average mean squared error (MSE), which is propagated back to adjust the interconnection weights to minimize the error of prediction in next epochs. Due to the constant check of previous errors and update of learning parameters, the algorithm is called a “back propagation” algorithm. Depending on the complexity of the problem, 1500–2500 epochs may be needed. However, this is a critical process and the number of neurons and epochs should not be too high to avoid the system memorizing the patterns instead of learning them. Memorization may give successful training errors between predicted and actual outputs, but the system may fail in performance in the face of new inputs in test cases. Training may involve trials with different numbers of hidden layers and neuron quantity to find the best combination that can give an acceptable error with a preferably smaller, but robust, network.

Batch learning, where the error is stored up to the end of all training examples before the system is updated, is more stable and more common. During learning process, interconnection weights and learning rates are adjusted with change parameters, called step size and momentum (Fig. 1). Step size controls the change of weights, whereas momentum provides the properties from the previous weight update to make sure that the solution proceeds in the same direction as the previous iterations. During error minimization, a momentum factor between 0 and 1 is applied at each layer to increase the effective step size in shallow regions of the error surface and to move the solution toward a global optimum without being stuck at a local optimum. Also, the weight update for a given error, or “learning rate,” is controlled by a small number called the “step size.” These parameters are not static and

can be adjusted to obtain a lower error and more efficient error minimization.

Once the training phase is complete, the performance of the network needs to be validated on an independent data set using “cross validation.” Cross validation is a model evaluation method that gives an indication of how well the MLP will behave with new data. It is important that the validation data should not be part of training set. Cross validation is further followed by testing to evaluate the performance of the MLP. Due to the multiple stages of learning and testing, MLP usually requires a large dataset to be trained and optimized. Therefore, the available data should be randomized to avoid biases, normalized, and then partitioned for training, cross validation, and testing phases.

Which Inputs to Use? Reducing Dimensionality

MLP can tackle multivariate problems to find relations between different input and output patterns. An increased number of input parameters increases the need for using more hidden layers and neurons in each of the hidden layers. Also, some of the input parameters may not be as influential or may be highly correlated with others. Therefore, it is advantageous to reduce the number of input parameters in such a way as to reduce the dimensionality of the network but still to cope with the complexity, nonlinearity, and multivariable nature of the problem. Performing a principle component analysis (PCA) externally and prior to MLP development may help to reduce the complexity of the problem and allow for a more targeted search of the relations between inputs and outputs. Hybrid models can also address the complexity reduction issue internally, although presenting a large number of inputs to the MLP by relying on the network to determine the critical model inputs usually increases network size. Such models that select variables automatically, and thus eliminate the knowledge and expertise of the user, can be used when the modeled system is not well understood. If the contribution of each input parameter is understood, there are distinct advantages in using statistical methods, such as PCA, to determine the inputs prior to developing MLP models. One other advantage of reducing input variables is that more input-output patterns require more training data. Therefore, especially, if the training data are limited, it is advantageous to limit the number of inputs to only significant ones.

Summary and Conclusions

MLP-type ANN networks can perform function approximation and classification successfully, and they have been implemented in various software packages. Depending on

the nature of the problem and its complexity, the data requirements can be significant for a robust network. Therefore, employing a statistical method beforehand to determine significant parameters for the problem can reduce the network size and training data requirements. Also, the MLP performance can be improved by adjusting the network architecture, transfer functions, and learning parameters during the training phase. The objective of developing an MLP-type ANN should be minimization of training, cross validation, and testing errors; and developing it so that the network will not just memorize the patterns in the dataset at hand but will be flexible to model completely new data.

Multiphase Flow

Juliana Y. Leung
University of Alberta, Edmonton, AB, Canada

Definition

A fluid phase refers to a homogeneous region of matter. It may consist of more than one chemical component. Phases are separated by distinct boundaries. For example, an aqueous

phase consists of water (H₂O) and other water-soluble solutes. In the context of mathematical geosciences, multiphase flow refers to the flow of more than one fluid phase simultaneously through a porous medium.

Introduction

Multiphase flow in geologic media is of great importance in a variety of subsurface engineering problems. In this entry, the fundamental mathematical formulation of the governing equations and relevant constitutive relationships are discussed. Solution approaches to these problems are highlighted. Finally, areas of current investigations and knowledge gaps are examined.

Mathematical Formulation of Multiphase Flow

The conservation of mass for component $i \in I, I = \{1, 2, \dots, N_c\}$ can be formulated as (Bird et al. 2007):

$$\frac{\partial \left[\phi \sum_{j=1}^{N_p} \rho_j S_j \omega_{ij} + (1 - \phi) \rho_s \omega_{is} \right]}{\partial t} = -\nabla \sum_{j=1}^{N_p} \left(\rho_j \omega_{ij} \vec{u}_j - \phi S_j \rho_j \vec{D}_{ij} \cdot \nabla \omega_{ij} \right) + R_i. \quad (1)$$

N_c and N_p refer to the total number of components and phases, respectively. R_i the source or sink term. ϕ and ρ_s denote porosity and solid density, respectively; ρ_j and S_j are the density and saturation of phase j . ω_{ij} and ω_{is} represent the mass fractions of component i in phase j or the solid (rock), respectively. $\vec{D}_{ij}$ is the dispersion tensor. For a special case with three components of water ($i = 1$), “oil” ($i = 2$), and “gas” ($i = 3$), if dispersion and fluid-rock interaction (e.g., adsorption) are omitted, the conservation of mass becomes:

$$\frac{\partial \left(\phi \sum_{j=1}^3 \rho_j S_j \omega_{ij} \right)}{\partial t} = -\nabla \sum_{j=1}^3 \rho_j \omega_{ij} \vec{u}_j + R_i. \quad (2)$$

It is further assumed that three immiscible phases exist: aqueous ($j = 1$), oleic ($j = 2$), and gaseous ($j = 3$). It is generally expected that the water component would be present only in the aqueous phase, while the oil and gas components may partition into both the oleic and gaseous phases. This conceptual model is described as a black-oil model, where “oil” and “gas” refer to the liquid and vapor

hydrocarbons at standard (surface) conditions, respectively. The conservation of mass for each phase is written as:

$$\text{Water : } \frac{\partial(\phi \rho_1 S_1)}{\partial t} = -\nabla \cdot (\rho_1 \vec{u}_1) + R_1; \quad (3)$$

$$\begin{aligned} \text{Oil : } & \frac{\partial[\phi(\rho_2 S_2 \omega_{22} + \rho_3 S_3 \omega_{23})]}{\partial t} \\ & = -\nabla \cdot (\rho_2 \omega_{22} \vec{u}_2 + \rho_3 \omega_{23} \vec{u}_3) + R_2; \end{aligned} \quad (4)$$

$$\begin{aligned} \text{Gas : } & \frac{\partial[\phi(\rho_2 S_2 \omega_{32} + \rho_3 S_3 \omega_{33})]}{\partial t} \\ & = -\nabla \cdot (\rho_2 \omega_{32} \vec{u}_2 + \rho_3 \omega_{33} \vec{u}_3) + R_3. \end{aligned} \quad (5)$$

Conservation of momentum in a porous medium is represented by Darcy's law (Bear 1972). The superficial velocity of phase j is denoted as $\vec{u}_j$:

$$\vec{u}_j = -\vec{k} \frac{k_{rj}(S_j)}{\mu_j(\omega_{ij}, \vec{u}_j)} \cdot (\nabla P_j + \rho_j \vec{g}); \quad (6)$$

$\vec{k}$ is the permeability tensor; $\vec{g}$ is the gravitational vector along the vertical direction; P_j , μ_j , and k_{rj} are the pressure, viscosity, and relative permeability, respectively, for phase j ; $\vec{\lambda}_j$ is the phase mobility tensor. It should be noted that Darcy's law is an approximation to the full conservation of momentum when the Reynolds number is approximately zero:

$$\frac{\partial(\rho_j \vec{v}_j)}{\partial t} = -(\nabla \cdot \rho_j \vec{v}_j) \vec{v}_j - \nabla \cdot \vec{\tau}_j - \nabla P_j - \rho_j \vec{g}. \quad (7)$$

$\vec{\tau}$ is the shear (deviatoric) stress tensor, and $\vec{v}$ is the interstitial velocity. Equation (7) can be simplified to Eq. (8) at steady-state conditions with low velocity:

$$\nabla \cdot \vec{\tau}_j = -\nabla P_j - \rho_j \vec{g}. \quad (8)$$

It can be shown that Darcy's law is obtained when setting $\nabla \cdot \vec{\tau}_j = \vec{\lambda}_j^{-1} \cdot \vec{u}_j$.

Constitutive Relationships

When multiple fluids are occupying a pore space, various types of interfacial forces would act between the fluids and the rock matrix. The distribution of these fluids within the

pore space (e.g., phase saturation, S_j) directly affects their transport behavior (e.g., phase relative permeability, k_{rj}).

Wettability is related to the interactions between the fluids and the solid. If two fluids are contacting a rock matrix (solid surface), the fluid whose molecules exhibit the strongest affinity for the atoms in rock will likely occupy much of the surface. Considering a system consisting of a solid (s) and two fluids (fluid-1 and fluid-3), the spreading coefficient (S) is defined as follows (Adler 1995):

$$S = \sigma_{s1} - \sigma_{s3} - \sigma_{13}. \quad (9)$$

where σ_{s1} , σ_{s3} , and σ_{13} are the interfacial tensions for the solid-fluid-1, solid-fluid-3, and fluid-1-fluid-3 interfaces, respectively. **Interfacial tension** is related to the imbalance of forces at the interface; it represents the differences in molecular attraction for molecules in the same phase, as opposed to the molecular attraction for molecules in another phase. If $S > 0$, fluid-3 is wetting the solid surface completely, with a contact angle of zero; otherwise, fluid-3 is only partially wetting the solid surface. **Contact angle** (θ) refers to the angle at which the interface between two fluids is intersecting the solid surface. It is defined according to Young's equation:

$$\cos \theta = \frac{\sigma_{s1} - \sigma_{s3}}{\sigma_{13}}. \quad (10)$$

If $\theta < 90^\circ$, fluid-3 is the wetting phase; if $\theta > 90^\circ$, fluid-1 is the wetting phase; if $\theta = 90^\circ$, the surface is neutral wet to both fluids.

If we consider the scenario where the non-wetting fluid (e.g., fluid-1) is injected into a rock sample, two cases would be observed. In the first case, if fluid-1 is present in a pore body and a connected (neighboring) pore throat is filled with a wetting fluid (e.g., fluid-3), fluid-1 would not spontaneously enter the pore throat; in fact, it only enters the pore throat if its pressure is greater than the pressure in fluid-3 by a certain threshold, which is the **capillary pressure** (P_c):

$$P_c = \sigma_{13} \left(\frac{1}{r_1} + \frac{1}{r_2} \right) = \frac{2\sigma_{13}}{r}. \quad (11)$$

The principal radii of curvature of the interface between the two fluids are denoted as r_1 and r_2 , while r is an "effective" radii of the interface. Capillary pressure is related to the difference in fluid pressure across an interface between two immiscible fluids in a confined space, such as a pore throat or a tube.

In the second case, the non-wetting fluid is present in a pore throat and a connected pore body is filled with a wetting fluid. There now exists an excess capillary pressure (ΔP_c), as given in Eq. (12). It is the difference in P_c for an interface in

the throat and the pore body. As a result, the non-wetting fluid would spontaneously enter the connected pore body.

$$\Delta P_c = \frac{2\sigma_{13}}{r_t} - \frac{2\sigma_{13}}{r_b} = 2\sigma_{13} \left(\frac{1}{r_t} - \frac{1}{r_b} \right). \quad (12)$$

r_t and r_b are the effective radii of the pore throat and pore body, respectively. The invasion of a non-wetting phase or draining of the wetting phase is called a **drainage** process, while the invasion of a wetting phase is called an **imbibition** process. As the capillary pressure increases, more non-wetting fluid would fill the porous medium, resulting in P_c being a function of fluid saturation. The P_c -saturation relationships are used as a constraint or auxiliary equation when solving the governing equations. In particular, it describes the dependency in pressure among the different fluids across an interface.

If there are three fluids present in a porous medium, one of them would be the wetting fluid, while the other two would be the non-wetting fluids (fluid-1 and fluid-2). However, fluid-1 and fluid-2 may exhibit different fluid-solid interfacial behaviors. If $\sigma_{13} > \sigma_{23}$, fluid-1 is the non-wetting phase and fluid-2 is the intermediate phase. The spreading phenomenon for a three-phase system is more much complex; further discussion of this subject, as well as contact line determination for a three-phase system, can be found in the cited references (Adler 1995; Blunt 2017).

Darcy's law offers a convenient way to describe flow behavior at a macroscopic level. The **relative permeability**

coefficients, in particular, are used to capture the relevant pore-scale physics; therefore, these relative permeability functions are strongly dependent on the pore structure and pore size distribution (Parker 1989). A set of connected pore bodies and throats can be represented quantitatively (or numerically) using a pore network model, which consists of a 3D network of nodes and channels with varying sizes (e.g., radii and lengths). This approach has gained significant popularity with advances in image analysis and digital rock physics. Different levels of capillary pressure are applied to the network to simulate the drainage and imbibition processes, and the macroscopic relative permeability relationships, as well as capillary pressure relationships, can be computed as a function of phase saturations and saturation history (or paths) (Blunt 2017). Although such theoretical computations using pore network models are feasible, empirical functions derived from experimental measurements involving actual rock samples are still most commonly adopted. A schematic of two-phase relative permeability functions for the wetting (k_{rw}) and non-wetting phases (k_{rnw}) are shown in Fig. 1.

Residual saturation is the saturation at which the relative permeability becomes zero, as denoted by S_{wr} or S_{nwr} for the wetting and non-wetting phases, respectively, in Fig. 1. As a result of capillary pressure, the non-wetting phase preferentially occupies the bigger pore bodies or centers of pore throats, while the wetting phase preferentially occupies the smaller pore throats, crevices between rock grains. The trapped non-wetting phase would likely pose a bigger

Multiphase Flow,
Fig. 1 Typical two-phase relative permeability functions

obstacle to the flowing wetting phase than vice versa. As a result, k_{rw}^o is generally higher than k_{rw}^o . In addition, the crossover between the two curves would typically occur where the wetting phase saturation is greater than 0.5 (Bear 1972).

Analytical Formulations Versus Numerical Simulations

The aforementioned governing equations (conservation of mass and Darcy's law) are solved by incorporating the relevant constitutive relationships (relative permeability and capillary pressure functions), as well as other auxiliary relationships such as a phase behavior or fluid model (e.g., an equation of state). Solutions to these problems may involve both analytical and numerical techniques. Boundary and initial conditions must be specified to complete the problem statement. Examples of boundary conditions may include no-flow boundary or constant pressure or flux. Analytical solutions are popular because of their simplicity and ease of application. They are widely adopted in the areas of pressure transient analysis or well testing (Lee et al. 2003). However, many assumptions regarding the flow regimes (e.g., transient flow, boundary-dominated flow, sequential depletion) or model set-up (e.g., geometric symmetry and homogeneous properties) are often invoked in analytical models.

Simulations entail numerical approximation of the solutions to the governing equations. Despite some recent developments in unstructured mesh generation and finite-element formulations for simulating multiphase flow, most existing commercial simulation packages predominantly focus on finite-difference/finite-volume schemes. A variety of structured and unstructured meshes, including Cartesian, corner point, perpendicular bisector (PEBI), and Delaunay triangular/tetrahedral, grids are available. Further details can be found in (Chen et al. 2006). Meshes should conform to the domain boundaries. The overall computational requirement would increase with more complex meshes and local refinement. Upscaling, a process that aims to replace a fine-scale detailed description of reservoir properties with a coarser scale description that has equivalent properties, is often used to generate a coarser mesh (Das and Hassanizadeh 2005).

Current Investigations and Knowledge Gaps

Much of the current research efforts have been focusing on the incorporation of additional physical phenomena. For example, coupling multiphase flow with geomechanical and geochemical considerations under non-isothermal conditions. This would require incorporating additional governing and auxiliary equations, such as energy balance, linear

momentum balance, and complex reaction kinetics, into the solution process. These coupled simulations are important for modeling more complex subsurface systems, including geothermal reservoirs, geologic storage of CO₂, and unconventional tight/shale formations with irregular multiscale fracture networks. More sophisticated numerical approximation or discretization methods (e.g., advanced finite element methods with mixed spaces) are needed to enhance computational efficiency and better capture the complex physical processes or geometries, which often introduce additional nonlinearities among the model parameters.

Another main challenge is the discrepancy between measurement and modeling scales, as well as the difficulty in representing heterogeneity (and its uncertainty) at these different scales. Detailed pore-scale models are computationally expensive and not suitable for field-level analysis. Macroscopic models are often employed. Darcy's law, in theory, is only applicable at scales greater than or equal to the representative elementary volume (REV) scale (Bear 1972). However, heterogeneity generally varies with scale. As a result, quantifying the sub-scale variability in multiphase flow and transport behavior, due to uncertain heterogeneity distribution below the modeling scale, is especially challenging (Vishal and Leung 2017).

Summary or Conclusions

Subsurface multiphase flow problems are encountered in a wide range of scientific and engineering applications. Complex heterogeneity observed in rock properties coupled with multitudes of physical phenomena render these problems to be both challenging and interesting. Models at both the pore- and macroscopic-levels are commonly adopted to analyze these problems. Future directions should focus on discovering, examining, and quantifying additional physical phenomena into existing or new models.

Multiple Correlation Coefficient

U. Mueller

School of Science, Edith Cowan University, Joondalup, WA, Australia

Definition

Given a set of random variables $\{X_1, X_2, \dots, X_K\}$, the multiple correlation coefficient $\rho_{X_i(X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_K)}$ of the i^{th} random variable X_i on the remaining $K - 1$ variables is given by

$$\rho_{X_i(X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_K)} = \sqrt{1 - \frac{\det(C(X))}{\det(C_i(X))}},$$

where $C_i(X)$ is the i^{th} principal minor of the correlation matrix

$$C(X) = \begin{bmatrix} 1 & \rho_{X_1 X_2} & \cdots & \rho_{X_1 X_K} \\ \rho_{X_2 X_1} & 1 & \cdots & \rho_{X_2 X_K} \\ \vdots & \vdots & \ddots & \vdots \\ \rho_{X_K X_1} & \rho_{X_K X_2} & \cdots & 1 \end{bmatrix},$$

i.e., the matrix obtained by removing the i^{th} row and the i^{th} column of $C(X)$ and $\rho_{X_i X_j}$ is the Pearson correlation coefficient between X_i and X_j .

Properties and Usage

The multiple correlation coefficient was first introduced by Pearson (1896) who also produced several further studies on it and related quantities such as the partial correlation coefficient (Pearson 1914). It is alternatively defined as the Pearson correlation coefficient between X_i and its best linear approximation by the remaining variables $\{X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_K\}$ (Abdi 2007). In contrast to the Pearson correlation coefficient between two random variables, which attains values between -1 and 1 , the multiple correlation coefficient is

nonnegative. In particular, the multiple correlation coefficient is equal to 0, when the random variables in $\{X_1, \dots, X_K\}$ are pairwise orthogonal, i.e., when $C(X) = I_K \times K$, i.e., when $\rho_{X_i X_j} = 0, i \neq j$. On the other hand, when the random variables in $\{X_1, \dots, X_K\}$ form a closed composition (see ► “Compositional Data”), which is a common situation when considering geochemical data, then $\rho_{X_i(X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_K)} = 1$ for all $i, i = 1, \dots, K$. This property reflects nothing other than the constant sum constraint of compositional data, as the correlation matrix for the independent variables has 0 determinant.

The multiple correlation coefficient can be used to measure the degree of multicollinearity between variables as follows. The variance inflation factor VIF_i for the i^{th} variable (Hocking 2013) is defined as

$$VIF_i = \frac{1}{1 - \rho_{X_i(X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_K)}^2}.$$

Its value is nonnegative, and it increases with decreasing magnitude of $\rho_{X_i(X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_K)}$. There is a high degree of collinearity in the data if $VIF_i > 10$, for some $i, i = 1, \dots, 10$.

The most common application of the multiple correlation coefficient arises in the situation when there is a dependent variable Y and a set of predictor or dependent variables $\{X_1, X_2, \dots, X_K\}$. In this case, the multiple correlation coefficient may be computed from the matrix

$$C(Y, X) = \begin{bmatrix} \rho_{YY} & \rho_{YX_1} & \cdots & \rho_{YX_K} \\ \rho_{X_1 Y} & \rho_{X_1 X_1} & \cdots & \rho_{X_1 X_K} \\ \vdots & \vdots & \ddots & \vdots \\ \rho_{X_K Y} & \rho_{X_K X_1} & \cdots & \rho_{X_K X_K} \end{bmatrix}$$

as

$$\rho_{Y(X_1, X_2, \dots, X_K)} = \sqrt{1 - \frac{\det(C(Y, X))}{\det(C(X))}}$$

and the multiple correlation coefficient $\rho_{Y(X_1, X_2, \dots, X_K)}$ as a measure between the dependent variable and its predictors is well defined, and it does not matter whether the independent variables are random or fixed (Abdi 2007). The multiple correlation coefficient attains a particularly simple form, when the independent variables are pairwise orthogonal (Abdi 2007), in that case it is given as the sum of the square correlation coefficients:

$$\rho_{Y(X_1, X_2, \dots, X_K)} = \sqrt{\rho_{X_1 Y}^2 + \rho_{X_2 Y}^2 + \cdots + \rho_{X_K Y}^2}$$

This case arises, for example, when a regression is based on principal components (see ► “Principal Component Analysis”).

In regression settings, the square multiple correlation coefficient is interpreted as the fraction of the variation in the data explained by the model; this quantity is also known as the coefficient of determination.

The coefficient of determination $R^2_{Y(X_1, X_2, \dots, X_K)}$ is commonly used as one of the criteria for determining the best model from a set of competing regression models. As $R^2_{Y(X_1, X_2, \dots, X_K)}$ is biased upward, the adjusted R^2 is normally considered which is nothing other but $R^2_{Y(X_1, X_2, \dots, X_K)}$ multiplied by $\frac{n-1}{n-K-1}$ where n denotes the number of observations.

To test whether a given value of $R^2_{Y(X_1, X_2, \dots, X_K)}$ is statistically significant, the ratio

$$F = \frac{R^2_{Y(X_1, X_2, \dots, X_K)}}{1 - R^2_{Y(X_1, X_2, \dots, X_K)}} \times \frac{n - K - 1}{K}$$

is computed, and under the assumption of normally distributed errors and independence of the errors and estimates, this ratio follows an F -distribution with K and $n - K - 1$ degrees of freedom (Abdi 2007).

The usefulness of $R^2_{Y(X_1, X_2, \dots, X_K)}$ is context dependent: a low value which is statistically significant might be acceptable when the aim is to discover causal relationships, but even a relatively high R^2 might be unacceptable when accurate prediction is required (Crocker 1972). Already in 1914 Pearson cautioned about the temptation to add more variables with the aim to increase significance; this strategy will only succeed, if the variables to be added have weak correlation with the other predictors and among one another and high correlation with the dependent variable (Pearson 1914). It should be noted that multiple correlation or coefficient of determination is rarely used on their own when judging the quality of a statistical model but typically in combination with the Akaike or Bayes information criteria (James et al. 2013).

Applications

The multiple correlation coefficient is rarely used as a measure for the goodness of fit of a regression model. It is more common to use the coefficient of determination for this purpose. Exceptions are a study by Liu et al. (2019) in a context of fully mechanized coal mining where the height of the water conducting fractured zone in is modeled via nonlinear multiple linear regression with predictor variables thickness of coal seam, proportion of hard rock, length of panel, mined depth, and dip angle. The model is tested in detail for the Xiegou coal mine in the Shanxi Province, China. The multiple regression coefficient has also been used to evaluate competing models in mineral prospectivity mapping such as the case study on

iron ore presented by Mansouri et al. (2018). The general setting for these evaluations is often cross-validation.

In a geostatistical context, multiple correlation is also typically used in cross-validation as one criterion in the assessment of the quality of a geostatistical model (Webster and Oliver 2007).

Summary

The multiple correlation coefficient is a measure of association linked to multiple regression and is useful as a first-pass measure for assessing the quality of a regression model. In this case, it is calculated as the Pearson correlation between estimates and true values. However, it is also a valuable tool to appraise the input variables and their potential for variance inflation.

Definition

Multiple-point geostatistics is the field of study that focuses on the digital representation of the physical reality by reproducing high-order statistics inferred from training data, usually training images, that represent the spatial (and temporal) patterns expected in such context. Model-based and data-driven algorithms aim to reproduce such patterns in space-time by capturing and reproducing real world features through trends, hierarchies, and local spatial variation.

Multiple-point Geostatistics: A Historical Perspective

Geostatistics aims at modeling spatio-temporal phenomena, which encompasses a large class of types of data and modeling problems. From a niche statistical science in the 1970s, it has now evolved into a widely applicable and much used set of practical tools. The increased acquisition of massive spatio-temporal data and the vast increase in computational power is at the root of a renewed attraction to geostatistics. Fundamental societal problems, such as climate change, environmental destruction, and even pandemics, involve spatio-temporal data. Solution to these problems will require ingesting vast datasets while treating them in a repeatable, coherent, and consistent mathematical framework. Such coherent framework was first established by George Matheron (Matheron 1973), with the formulation of random function theory and extension of random variables to space-time. Space-time is more challenging than multivariate problems, since, as he discovered, mathematical models are required that address the special continuity that is space-time. While in multivariate analysis (Härdle and Simar 2015), covariance matrices are fundamental building block, geostatistics requires functions, such as covariance functions that need to be defined mathematically consistently (Matheron 1973), in as much as the covariance matrix needs to be positive definite to be useful in multivariate statistics.

For the first three decades, geostatistics followed classical principles outlined in probability theory. Estimating spatio-temporal behaviors was cast as a least-square problem of estimating stochastic functions. The unbiased linear solution to this least square formulation of the estimation problem was termed kriging (Matheron 1963). Kriging is one of the most general forms of linear regression, where all (linear) dependencies are accounted for. Today we see a resurgence of kriging in Computer Science and Machine learning, in the form of Gaussian process regression (Rasmussen and Williams 2006). Regression does not provide an uncertainty quantification on a function. The estimated functions are smoother than the true functions because covariance between the function and the data is not equal to the covariance of the data itself. A regression estimate is not necessarily a reflection of truth or true behavior. The quest for “truth” arrived in the form of stochastic simulation (e.g., Lantuéjoul 2013; Deutsch and Journel 1998). Instead of one best guess function, the aim is to build realistic models of the real world, where realism is, at least initially, based on modeling statistical properties of the data. In traditional geostatistics, a key statistical property is the semi-variogram, which essentially described the average square difference in value between any two locations in space. A marriage was found between variograms (covariances) and the multivariate Gaussian distribution. The Gaussian assumption was essentially needed because it leads to convenient analytical expressions that involved the variogram. As we now know, much of statistics in the nineteenth and twentieth century was driven by analytical closed form expressions, simply because of lack of computer power. Parsimonious parametric models, such as multi-Gaussian random fields, require estimating just a few parameters. Today, machine learning involves estimating possibly millions of parameters from even more data. A much due makeover in Geostatistics was arriving.

There was a cost to analytical convenience and that cost was physical plausibility and/or truthful behavior. Spatio-temporal models based on variance reflected the (linear) spatial correlation in the data but nothing more. The parsimonious part often led to a fairly narrow formulation of spatial uncertainty. As a result, geostatistical simulation models were often not “believed” by practitioners (Caers and Zhang 2004). This was certainly true in the natural sciences, for example, geology, where practitioners come with a background and prior knowledge about what they believe is truthful about spatial variation. In that context, spatial variation can be distinct and organized in a fashion that cannot be captured with linear models of correlations, such as variograms and Gaussian regressions. Nature is often organized in very specific geometries: forms of low-entropy type of variation and

not high-entropy such as a Gaussian distribution with given covariance.

In the late 1990s, it now became clear that just the measured data of the phenomenon at the study area of interest may not be sufficient and that additional prior information is required (Strebelle 2002; Guardiano and Srivastava 1993). And, alternatively, that so much data is available that parametric models can no longer describe their statistical complexity. The analogy to machine learning is now clearly visible: a model should be trained with data from “something else,” then applied, that is, generalized to the problem at hand. Since geostatistics deals with spatio-temporal data, the training data would need to be of that kind, somewhat exhaustive in space-time. The training image was born. The word “image” here reflects the spatial coherence of such data, just like the covariance function is mathematically consistent. Training “images” can be 4D (space-time). Training images are by definition “positive definite,” simply because they exist in the real world: every single statistic extracted from a training image, such as an exhaustive experimental variogram is, by definition, positive definite. With the advent of the training image, or some very large exhaustive dataset of space-time, came the decrease in the need for parsimonious parametric models. In fact, most algorithms in MPS, but not all, are decidedly nonparametric: the data is driving the model. Because now a large amount of data are available, statistical properties other than the variogram became accessible, simply because of the increase in frequency of observations. MPS algorithms described in the next section rely heavily on this fact. Calculations can now be made of the probability of occurrence at some location, given any values in the neighborhood (space-time), without a probability model, simply by counting. Alternatively, comparisons can be made between some pattern of data in the study area of interest and the patterns in the training image. This comparison, in terms of “distance,” leads to the birth of many MPS algorithm, some of which mimic ideas in computer graphics such as texture synthesis (Mariethoz and Lefebvre 2014).

Applications have always driven development in geostatistics. MPS was driven by such need as well as the explosion of data and computational power. While MPS focused initially on oil and gas applications (a funding reason), it has lately expanded to many fields of the Earth Sciences and beyond. The oil and gas application is worth mentioning because of the direct link between the realistic depiction of geological geometries and realism in the multiphase flow oil/water/gas in the subsurface (Caers 2005; Pyrcz and Deutsch 2014). Real-world applications drove the development of MPS. Current needs are also driven by ease of use. Fitting higher-order parametric statistical models (Mustapha and Dimitrakopoulos 2011) is extremely challenging even for a statistical expert, let alone the thousands of possible

nonexpert users. A certain form of expertise is needed. Current work in science is more going towards artificial intelligence, meaning procedures and processes that allow for relatively easy automation without the presence of the expert. The 1970s expert-based way of doing geostatistics is gradually diminishing simply due to the current technological revolution. MPS algorithms now are evolving to this form of self-tuning (e.g., Meerschman et al. 2013; Baninajar et al. 2019), because they rely on relatively small amounts of tuning parameters that can be learned from examples. In these types of algorithms, there is no need to assess convergence in a Markov chain, or worry about positive definite functions. This allows the domain of application to continue growing as more people discover the richness and convenience that MPS approaches bring to their real world.

Methods

Simulation methods aim at generating multiple renditions of a random function, honoring conditioning data and reproducing a spatio-temporal structure, as depicted in the training information. In some cases, the goal is one of realism, where the reproduction of exact statistics of pattern configurations may not be a priority. In other cases, the goal is to match as closely as possible the multiple-point pattern frequencies, while respecting conditioning data. In order to solve this problem, various approaches have been developed over the last 30 years, from methods that attempt to solve this analytically, to methods that rely on the heuristics of a specific algorithm to define the higher-order patterns found in the resulting realizations. A review of all the methods is available in the book by Mariethoz and Caers (2015).

In this section, we provide some basic definitions and then dive into a high-level description of different methods and their differences.

Definitions

MPS simulation methods aim at reproducing patterns consistent with some reference information, often a training image, thereby characterizing the spatial (or spatio-temporal) continuity of one or more variables. Patterns are specific configurations of values and locations/time (Fig. 1). Furthermore, in practice, the pattern is composed of conditioning data, which may include previously simulated nodes, and the simulated node or patch, where values need to be assigned. This is referred to as a data event (Fig. 2). In order to inform the simulated node or patch, the training image is used to identify the frequency of values taken by the simulated nodes (red nodes in Fig. 2). An exact match or a similar pattern may be sought after, however, nodes within the simulated patch

Multiple Point Statistics, Fig. 1 The concept of a pattern: the pattern is defined within its domain (the grey area) by the specific data values taken by one or more variables at multiple locations and times. In the example, values can be “black” or “white,” representing two categories. Locations are defined relative to a specific position in space and time (in this case, the center x , at time t)

should be matched exactly, or at least more closely, as these are key to avoiding artifacts in the simulation result.

The continuity of the spatio-temporal information is inferred from the training data, by recording the occurrence/nonoccurrence of a specific data event, by sampling or scanning the training image. This provides information about possible values the simulated node or patch may take.

Simulation Methods

A large variety of approaches exists to generate simulated models accounting for multiple-point statistics. As discussed in Sect. 1, most of these methods are driven by the algorithm; however, there are a few exceptions where the random function is analytically defined (model-based approaches) and a full description of the mathematical model that characterizes the statistical and spatial frequency of patterns is available. Algorithm-based methods, on the other hand, do not explicitly define the probability model. The conditioning data and

Multiple Point Statistics, Fig. 2 The concept of data event: the data event defines the relationship between the location (in space and time) of the conditioning values and the node or patch (as in this example) to be simulated. In this case, the patch to be simulated consists of 3 by 3 pixels, from which two are already informed. In addition to these two nodes, 11 additional conditioning points are available, some of them from a previously simulated patch (at the bottom of the domain)

frequency of different patterns, inferred from the training information, impose feature in the simulated models, but some features are a direct result of the algorithm.

Model-based Methods

Among model-based methods, Markov Random Fields (MRF) (Tjelmeland and Besag 1998) can be used to reproduce joint and conditional distributions of categorical variables by defining the interactions between pixels in the simulation grid. Reproduction of large-scale continuity can be achieved by imposing high-order interactions (beyond pairwise relationships), over a limited neighborhood. The conditional probability at a specific location $\mathbf{x}_i$ conditioned to the data event, $p(z(\mathbf{x}_i)|N(\mathbf{x}_i))$, is modeled as an analytical function, usually an exponential function (parametric model), from which the spatial law of the random function can be fully defined (up to a normalization constant). Conditional distributions can also be written as an exponential function:

$$p(z(\mathbf{x}_i)|N(\mathbf{x}_i)) \sim \exp\left(-\sum_{c:\mathbf{x}_i \in C} V_c(z_c)\right)$$

where z_c is a clique (a set of connected nodes within the pattern), V_c is a potential function that defines the parametric interactions between cliques. The challenge of MRF is to determine which cliques should be used and how to infer

the parameters θ of the potential functions. This is approached in theory by maximum likelihood; however, in practice it requires Markov chain Monte Carlo sampling, in order to approximate the likelihood function.

Markov mesh models (MMM) are a subclass of MRF that solve some of these implementation issues. They essentially work as a two- or three-dimensional time series. The conditioning path is kept constant, that is, a unilateral path is used, thus simplifying the problem and limiting the clique configurations. Furthermore, the potential functions can be parameterized by using generalized linear models, with parameters inferred by maximum likelihood estimation.

A second family of methods under the model-based category builds upon the concept of moments of the random function. Instead of limiting the inference and simulation to second-order moments as in Gaussian simulation, higher-order moments are considered. These are called spatial cumulants. This allows characterizing random functions with high-order interactions that depart from Gaussianity, thus imposing particular structure and connectivity of patterns. As with traditional variograms (or covariances), inference becomes an issue, thus requiring abundant training data.

Algorithm-based Methods

Many of the algorithm-based methods work under the sequential simulation framework. This means that every new simulated node or patch is conditioned by the hard data and previously simulated nodes within a search neighborhood. The typical sequential framework is summarized in Algorithm 1.

Algorithm 1

The sequential simulation framework

Inputs:

1. Variable(s) to simulate
 2. Simulation entity: pixel or patch
 3. Simulation grid and search neighborhood size
 4. Training data
 5. Conditioning points
 6. Auxiliary variables
 7. Algorithm parameters
-

Algorithm:

1. Assign conditioning data to closest nodes in simulation grid
 2. Visit nodes according to a path
 - 2.1 Search for conditioning data in search neighborhood
 - 2.2 Compute the conditional probability of the variable(s) in the simulation entity conditioned by the data and previously simulated values in the neighborhood (and constrained also with auxiliary variables)
 - 2.3 Draw a value (pixel or patch) from the conditional distribution and assign to location
 3. Postprocess realization
-

Outputs:

1. Simulated grid fully informed, honoring conditioning data and replicating patterns inferred from training data
-

Algorithms vary in the way they handle conditioning to data, inferring of the conditional distribution of node or patch values, and storing frequencies of nodes or patterns conditioned to different data events. The simplest approaches involve simulating a single node, noted pixel-based. Nodes are visited in a random path and at every uninformed location, a search is performed for nearby informed nodes (either conditioning data or previously simulated). A data event is then searched and retrieved from the training data.

Pixel Based Sequential Methods

The simplest method called Extended Normal Equation Simulation (ENESIM) directly scans the training image to determine the frequency with which the uninformed node to be simulated takes different values when conditioned by the data event (Guardiano and Srivastava 1993). This rather inefficient approach of scanning the training image every time can be improved by prescanning the training image and storing the different data events in a data structure for efficient retrieval. The Single Normal Equation Simulation (SNESIM) does this by using a search tree (Strebelle 2002), while the Improved Parallel List Approach method (IMPALA) uses a list (Straubhaar et al. 2011). Direct sampling (DS) replaces the inference of the full conditional distribution by finding a single case and using it as a direct sample of it (Mariethoz and Caers 2015).

Patch Based Sequential Methods

Other approaches seek faster results and a better reproduction of textures, by simulating a complete patch instead of a single node. The process is similar to the one for pixel-based methods. The specific data events as related to the patch to be simulated are inferred from the training image and stored either individually, grouped with a clustering technique or in some kind of data structure.

Stochastic Simulation with Patterns (SIMPAT) was originally conceived to perform this task creating a database of patterns, where the most similar to the data event is searched (using a distance metric). This makes it computationally expensive, which can be solved by clustering patterns that are similar into prototypes. This is done in several methods, where patterns are clustered after applying a dimensionality reduction technique. FILTERSIM uses filters to reduce the dimension of the feature space and then identify the most similar prototype to the data event. Based on this, a patch is drawn from the patterns within a prototype family. DISPAT performs a multidimensionality scaling (MDS) and clustering is done over this reduced space. WAVESIM uses wavelets coefficients for the pattern classification task.

Another variation of SIMPAT is provided by GROWTHSIM that uses a random path that starts at conditioning data locations and grows from there.

Pixel and Patch Based Unilateral Methods

Following ideas from texture synthesis (and similar to MMM), some methods use a unilateral path, instead of proceeding in the traditional sequential fashion with a random path. PATCHWORK simulation computes transition probabilities between patches in the unilateral path from the training image and draws from them depending on the data event, discarding patches that do not honor conditioning data in the nodes of the patch to be simulated. This approach is extended in cross-correlation based simulation (CCSIM), where the difference between patterns is computed rapidly by using a convolution with a cross-correlation distance function (Tahmasebi et al. 2014). Patches are drawn from the most similar set that matches the conditioning data. The patch can be split if no match is found, reducing the size of the simulated patches, thus simplifying the problem. Image Quilting (IQ) extends the CCSIM framework by optimizing the overlapping area between patches, using a minimum boundary cut.

Optimization Based Methods

Simulated annealing (SA) and Parallel Conditional Texture Optimization (PCTO-SIM) are optimization-based approaches (Mariethoz and Caers 2015). Both methods work by starting with the simulation grid filled randomly, except at conditioning locations, where the values are preserved. In SA, an objective function is defined to compute the mismatch between the current state of the simulation and the target statistics. These statistics are related to the frequency of patterns, which are inferred from a training source. A change in the current model is proposed, either by perturbing a node or swapping pairs of nodes, and the objective function is updated. Changes are conditionally accepted following the Boltzmann distribution, that is, favorable changes, those that make the simulation closer to the target, are always accepted, while unfavorable changes are accepted with probability. The probability of this acceptance is reduced as the simulation progresses. In the case of PCTO-SIM, iterations over the initial grid are applied in order to update patches that lead to the minimization of the mismatch function. This is resolved with an expectation-maximization algorithm, which is used to update patches of the simulation. SA can be extremely slow and depending on the definition of the objective function, fail at reproducing realistic representations of the phenomenon at the end of the simulation. More recent methods based on deep neural networks integrate the image reconstruction capabilities of deep learning methods in the spatial context.

Constraining Models to Data

Up to this point, we have discussed the simple case where conditioning data is a hard data, that is, a sample value without uncertainty at the same support of the simulation pixel, and that measures the same variable being simulated.

However, many of the methods described in the previous section can be extended to deal with multivariate data, where both the simulation grid and the training image need to contain multiple correlated variables. In this case, the direct and multivariate distributions are relevant (both statistically and over space/time). The extension to the multivariate case brings inference problems due to the combinatorial nature of the problem. It becomes harder to find specific patterns and every comparison becomes more expensive.

The case of dynamic data related to flow properties and geophysical information bring a different challenge. These variables are related to the simulated variables, but in an indirect manner, often through nonlinear relationships. Adhering to the relationship between the primary variable and the nonlinear information requires a different approach, often done with a Bayesian approach, requiring the definition of a likelihood function. Implementing such an approach requires specifying the prior distribution and then sampling from the posterior distribution according to Bayes' formulation. The prior can be based on training images; however, training-image based priors need to be consistent with data. If there is inconsistency, the sampling process may not converge to the posterior distribution.

Training Images

Requirements for a Training Image

Obtaining adequate training images is one of the most fundamental requirements to be able to use MPS, and at the same time it can be the largest hurdle. MPS simulation methods extract information from the training image and store it in different forms (e.g., a search tree for SNESIM, a list for IMPALA or even keeping the training image in its original image form for DS). Regardless of storage format, the stored training information is thereafter used equivalently as a model in the simulation process. Therefore, whichever simulation algorithm is chosen, it can only perform as well as the quality of the training image it is provided. This begs the question of defining what a good training image is. We define below three essential criteria, namely: stationarity, diversity, data compatibility.

A first requirement is that the training image should be stationary. This means that all areas of the training image represent similar statistical characteristics, otherwise it would be virtually impossible to calculate meaningful higher order frequencies or conditional probabilities. Stationarity in the traditional geostatistical sense, such as second order intrinsic stationarity, is now extended to higher order statistics. While there are ways of using nonstationary training images, those work by segmenting the nonstationary training image into several subdomains that are themselves stationary. This segmentation can take the form of well-defined zones

(de Vries et al. 2009) or continuously varying features that are described with an auxiliary variable, which defines correspondences between areas in the training image and in the simulation (Chugunova and Hu 2008). However, in all cases each segmented zone should be itself stationary, meaning that it must present a degree of recurrence of similar statistical characteristics.

The second requirement is that the training image should be diverse, that is, large enough to capture the properties of interest. But here the term “large” should not be taken in terms of size (e.g., number of pixels or voxels), but in terms of information content. Specifically, one can use a relatively small training image if the goal is to simulate simple patterns. But for complex and diverse structures, the training image needs to represent the entire range of features and their variability. Essentially, the features of the training image have to be replicated sufficiently in order to represent their diversity. If those features are large, the training image has to be large enough to contain a sufficient amount of them. One way of increasing the diversity of patterns in a training image is to use transform-invariant distances (Mariethoz and Kelly 2011), which allow considering not only the patterns present in a training image, but also the ensemble of their transformations (e.g., rotations, affinity transforms).

Finally, the third requirement is that a training image should be compatible with data are available for the simulated domain. Most practical cases involve conditional simulation, and therefore, such data exist. It can be, for example, scattered point measurements in the case of simulating rainfall intensity based on in situ rain gauge measurements, line data if simulating a 3D geological reservoir with information from wells, or it can be a known secondary variable which has a given relationship with the variable to be simulated, such as in geophysics. In such cases, the statistical properties of the simulated variable should correspond to the statistics of the data, and here again such requirement goes beyond mean and

variance, but can include higher-order properties such as connectivity or the frequency of patterns. Validating a training image for data compatibility can be achieved in several ways. Often, one would compute the statistical properties of interest on the dataset and on a candidate training image. This can take the form of variograms (for point data), connectivity functions (if the data are spatially continuous, a requirement for computing connectivity metrics), or patterns frequencies (using specific patterns comparison algorithms that assess the frequency of spatial patterns in both training image and data). Examples of pattern comparison algorithms are given in Boisvert et al. (2010), Pérez et al. (2014), and Abdollahifard et al. (2019).

To illustrate our stated requirements, Fig. 3 provides some examples of inadequate training images, which are individually commented in the figure caption.

Data-Based Training Images

There are two main ways of obtaining adequate training images for a given simulation problem. The first one is in situations where large amounts of spatially registered data are available, such that the data themselves can be used as training image. Typical data-rich applications where data-based training images are common include geophysics, remote sensing, or time series analysis. Such cases can involve processes that repeat themselves in space (e.g., geophysical cross-sections across a valley, where measured transects are assumed to be statistically similar to unmeasured transects) or repetitions in time (e.g., repeated acquisitions of remote sensing imagery, where previous acquisitions are similar to acquisitions of the same area that have not yet taken place), or even a combination of both (e.g., a spatial network of weather stations that produce several meteorological time-series that show recurrent patterns in both space and time).

One issue with data-driven training image is that direct observation of natural processes often does not correspond to

Multiple Point Statistics, Fig. 3 Example of inadequate training images. From left to right: (a) A very repetitive training image that is overly redundant and could be reduced to a fraction of its size without loss of information. (b) A nonstationary training image where features on the right and left are fundamentally different. Such an image could however be used by defining stationary subdomains. (c) A nonstationary

image with a continuous gradation of colors and orientations implying almost repetitivity. (d) Circular structures resulting in nonstationarity. May be usable with an auxiliary variable that defines where each feature should be mapped in the simulation, or by using rotation-invariant distances

the requirements outlined above. While pattern diversity can be attainable if large amounts of data are at hand (e.g., with Earth observation satellites that generate daily terabytes of spatialized imagery), stationarity and data compatibility are often more problematic.

Natural processes are rarely stationary, often requiring detrending techniques to make them amenable for use as training images. The detrending can take many forms, depending on the type of nonstationarity to be addressed. One solution for large-scale trends is to separate the training image in two components: a deterministic trend and a residual, much like the traditional way of doing geostatistics. Under the assumption that such a decomposition is sufficient to describe the trend in the data, the residual component is then considered as stationary and used as training image (Rasera et al. 2020). Such a decomposition is common in time series simulation, where the trend can, for example, describe seasonal fluctuations in the mean and in the standard deviation of the data of a variable.

Data compatibility can also be an issue when using data-based training images. The typical recommendation is to find data that are representative of the modeled process; however, this can be difficult in practice. The training image generally does not have exactly the same statistical properties as the data. In many cases, this can be resolved by applying a transformation to the data, such as a histogram transformation, which results in the training image having the same distribution as the available data. Sometimes however the data transformation needs to be more complex. For example,

one may want to simulate the spatial features of a deltaic channelized river, but the only available training image has been acquired in high-water conditions and therefore the channels are broader than desired. In this case, a morphological transformation of the training image may be more appropriate, for example, by applying erosion or dilation operators. Interactive image transformation techniques have been proposed to either alter the proportion of categories in an image or “warping” an image to change its morphological characteristics while preserving the overall topology (Straubhaar et al. 2019). This is illustrated in Fig. 4.

Construction of Training Images

In many applications, the data are too scarce to provide data-driven training images. A typical case is the modeling of subsurface reservoirs, where the only data are often borehole cores which provide lithological information along 1D lines that represent only a very small proportion of the entire reservoir 3D volume. In these cases, using MPS requires to build a training image based on whatever information is available. The common approaches to achieve this often involve using other geostatistical methods (i.e., other than MPS) that can produce a realistic representation of the phenomenon to model. Several geostatistical methods are less data-hungry than MPS and still able to depict a high level of complexity. For example, object-based approaches have been commonly used to create 3D training images in reservoir modeling.

Multiple Point Statistics, Fig. 4 Illustration of image warping. (a) input image, (b) and (c) image after expansion and compression, (d) proportion of each category. (Figure from (Straubhaar et al. 2019))

Another way of constructing training images is by using process-based models. These models use physical laws to model the process of interest, for example, sediment transport (Sun et al. 2001) or terrain erosion (Braun and Willett 2013) or fluid flow in fractures (Boisvert et al. 2008). This is generally done by solving computationally demanding systems of partial differential equations. Process-based models are often deterministic, and in any case so expensive that it is often not possible to obtain more than one or a handful set of realizations, let alone to condition them to available data. MPS is then the ideal tool to use these few models as training images and expand them into a larger set of realizations that are statistically representative and moreover conditioned (Comunian et al. 2014; Comunian et al. 2014; Jha et al. 2015).

Applications

As in Part I, we will provide here more of a historical timeline of applications, partly to illustrate how MPS grew and how more applications entered the scene, how diversity of algorithms became linked to diversity of applications. Without doubt, the primary application of MPS was in reservoir modeling (Oil & Gas; Caers et al. 2003; Caers and Zhang 2004). Reservoir modeling (Pyrz and Deutsch 2014) requires building multiple realizations of several important properties such as lithology, porosity, and permeability. The purpose of these models is either appraisal or production planning. The latter requires simulation of multiphase flow. Flow simulation is sensitive not just to the magnitude in permeability but to the contrast between high and low permeability. This contrast, in the subsurface, offers itself in specific geological shapes, such as lithological or architectural elements, or due to diagenesis. The connectivity of high (or low) permeability is poorly characterized by Gaussian distributions with given covariance (the high entropy model). Often, multiple-point geostatistics offered a compromise between Boolean and pixel-based methods. Boolean methods are more difficult to constrain to data; hence, they can serve as training images once the objects are pixelized on a grid. In terms of approach, oil and gas application very much followed the “constructed” training image approach (see sect. 3). Well data (considered hard data) are scarce, yet geological interpretation based on them (as well as seismic) are very specific. Uncertainty in such interpretation was handled by proposing multiple training image. Validation of training images was often needed when integrating production data. Specific methods for training-image based inversion of flow data were developed (Caers 2003). To date, a range of algorithms are used in actual applications: SNESIM, DS, IQ. Like discussed in the previous section, there was initially confusion around the need for a stationary training. Model based on dense outcrop data or generated using

process methods are by very definition nonstationary. Either stationary training images are used in combination with seismic data, which offers a nonstationary trend in petrophysical properties (Caers et al. 2001), nonstationary images are accompanied by auxiliary variables (Chugunova and Hu 2008) (Fig. 5).

Groundwater modeling offers similar challenges compared to oil and gas, namely, in the realistic representation of subsurface heterogeneity. A more general similarity emerges, namely, these are problems with very few specific data (hard data, wells) and very specific information on variability of spatial geometries. A second type of application was then emerging which presents the exact opposite problem: very dense data.

With very dense data, we enter the realm of geophysical and remote sensing data. Such data sources are easier to get exhaustively than drilling wells and require either passive monitoring (remote sensing, gravity) or active source monitoring (electrical resistivity, seismic). Two types of problems occur in which MPS has started to play a role: data gap filling and downscaling.

Satellite data may present gaps because of cloud cover and orbital characteristics. Traditional approaches by filling gaps using kriging (Cressie et al. 2010) poses many problems. First, kriging provides only a smooth representation of actual data variability. Second, a computational problem occurs because of the need to invert very large covariance matrices. MPS provides a natural solution in that it uses the data itself to derive statistics to fill the gaps. Here, the neighboring data is the “training image,” although there is no explicit construction of such image. Gap filling is also needed with (subsurface) geophysical data. Often such data are collected along acquisition lines with certain line spacing. These linespaced data then need to be gap-filled to get a 2D or 3D realistic representation of the subsurface. Most geophysical inversion methods smooth the line data.

Downscaling constitutes a set of problems whereby coarse scale data or models are transposed to fine-scale resolution. This problem is not uniquely defined: given an upscaling process, one can devise many downscaled models from a single coarse model. Downscaling can be addressed in two ways. First, one may have areas (or space-time blocks) with both high-resolution and low-resolution data, which can be used as training data. Alternatively, one may have constructed, using physical models, high-resolution models that are then upscaled (another physical process) into low-resolution versions. An example presented here is the downscaling of topographic data in Antarctica.

Other applications worth mentioning are in mining. Mining is characterized by the availability of dense drill-hole data; hence, training images based on dense data can be constructed, then used in sparser drilled areas. MPS has also

Multiple Point Statistics, Fig. 5 One of the first real-world application of MPS, generation of a reservoir model using a training image, constrained to well and probability maps deduced from seismic. (From Caers et al. 2003)

applications in temporal modeling such as the modeling of rainfall time-series (Fig. 6).

Summary and Conclusion

We presented a historical overview of multiple-point geostatistics (MPS) as well as some ongoing trends in this area. Fundamental to multiple-point geostatistics is recognizing that spatial covariance or variogram-based methods fail to capture complex spatio-temporal variation. Training images, either as constructed formats or as direct real-world observations, are explicit expressions of such variations. The aim of MPS algorithms is to capture and reproduce essential higher-order statistics from training images, at the same time, conditioning to a variety of data. Algorithms can be divided into two groups: model-based or data-driven. Model-based algorithms rely on the traditional probability theory framework while data-driven method share ideas with machine learning

and computer graphics. Training images are required to have certain characteristics to be useable with the defined MPS framework: stationarity, diversity, and data compatibility. Stationarity is required to be able to borrow meaningful statistical properties. Diversity is needed to have enough quantity of such meaningful statistical information and compatibility means that the statistical properties cannot contradict with actual conditioning data. The application of MPS methods and ideas continues expanding. From the initial subsurface focus, applications have grown to address the need of today's societal challenges: the Earth's landscape, climate, and the environment. The fundamental idea of MPS and the shift it brought to geostatistics will be permanent. The algorithms, data, and scope of applications will continue to grow, for example, more recent publications have started to focus on generative models that replace training images with neural networks. An example is the Generative Adversarial Network (GAN) that can be trained once and possibly ported to a variety of application with minimal modification.

Multiscaling

Jaya Sreevalsan-Nair

Graphics-Visualization-Computing Lab, International
Institute of Information Technology Bangalore, Electronic
City, Bangalore, Karnataka, India

Definition

In several natural resource and environmental applications, e.g., mining, there exists a high degree of uncertainty in the information in the scenario (Sagar et al. 2018). This uncertainty can be addressed using *scale-dependent* phenomena. *Scale* in simple terms refers to the scope of observations in the respective physical dimensions, such as spatial length (Euclidean space) and time, or related spatial dimensions, such as image space. Multiple geological features occur at different scales in time and space, namely tectonic objects (faults, joints, etc.), sedimentary objects (bedding structures, etc.), intrusive and effusive objects (lava flows, dykes, etc.), and epigenetic objects (metamorphic units, etc.). They range in spatial scales of micrometers to kilometers, and the geophysical processes range in time scales of microseconds to millions of years.

Multiscaling is used to capture information at different scales where specific type of *locality* can be defined, e.g., spatial locality or temporal locality. This is especially necessary to faithfully model multiresolution data, which are

generated or acquired at multiple resolutions, by design. An illustrative example of multiscaling is in determining instantaneous friction and predicting time to failure in tectonic fault physics of slow earthquakes at the laboratory scale, and at the field scale (Bergen et al. 2019). The fault generated in the laboratory is effectively a single frictional patch in a homogeneous system, and a field fault in the earth is an ensemble of several frictional patches, occurring in heterogeneous earth materials.

Overview

The use of scale for studying physical models and simulations, and for analyzing data has been well known. However, this practice also contrasts with the ideal formulation of *scale-independent* entities in mathematics, e.g., “point” (Lindeberg 1998). In modern data scientific applications, scale-space theory has been extended to nonconventional spatial regions, e.g., images. Such applications are important in the domain, as multiscaling is applicable for modeling and simulation of geoscientific processes, and for data analysis for observed as well as simulated data of all types, including images. Multiscaling in image processing and computer vision is used to address scale-dependent variations in perspective, and noise generated during the image formation process.

Multiple scales naturally organize data in hierarchical structures, from coarsest to finest scales, i.e., from lowest to highest resolution or scope of information, presenting data in the form of a pyramid. Given the presentation of variability in the data, multiscaling also becomes a process by which uncertainty in the data and/or the data model can be alleviated. Uncertainty in data is owing to variability in the process that is being observed, which causes insufficiency in the sampling and/or quality of data. This type of uncertainty is called *aleatoric* or irreducible uncertainty. The other type of uncertainty stemming from the data model used owing to incomplete knowledge of the phenomenon is called *epistemic* or reducible uncertainty. Epistemic uncertainty may be reduced by adding more data. Generally, the aleatoric uncertainty tends to be scale dependent (Sagar et al. 2018), and multiscaling may be seen as a powerful tool to resolve this type of uncertainty.

The widely used multiscaling methods define scale as a contextually appropriate parameter, and focus on the best method of aggregating the information acquired at different scales. For LiDAR (light detection and ranging) point cloud analysis, local neighborhood can be a spherical one (Demantké et al. 2011) or k -nearest neighbors (Hackel et al. 2016), in which case the radius of the sphere or the integral neighbor count k is taken as the scale, respectively. For feature extraction applications, the multiscale aggregation methods include using information at an optimal scale (Demantké et al.

2011), concatenating information from all scales as a long vector (Hackel et al. 2016), or performing an appropriate *map-reduce* operation on the information from the different scales, e.g., averaging (Sreevalsan-Nair and Kumari 2017). Thus, the multiscaling approaches perform filtering, concatenation, or transformations, respectively.

Applications

There exist several different multiscaling applications in geosciences. Instead of an exhaustive survey, illustrative examples of multiscaling in spatial length, time, image space, and point clouds are discussed here.

Transfer functions are mathematical functions used to navigate the hierarchical structures of scales, i.e., for upscaling or for downscaling. Consider the example of transfer functions used in hydrogeology, which is a combined discipline of studying soil science (pedology) and hydrology to understand their interactions in the critical zone of the earth (Lin 2003). This involves studies at microscopic scale of length ($1\ \mu\text{m} - 1\ \text{cm}$), mesoscopic scale ($1\ \text{m}$), and macroscopic scale ($1\ \text{km}$). The microscopic structures include pores and aggregates, mesoscopic ones include pedons and catenas, and macroscopic ones include watersheds and regional and global regions. These structures also reflect varied temporal structures, going from minutes-days, days-months, to months-years, respectively. Given that the natural physical processes involve multiple scales, the process modeling, simulation, and data analysis also tend to involve multiscale bridging in the discipline. The different scales are incorporated in hierarchical structures of soil mapping and soil modeling, and these are used in generating different pedotransfer functions (PTF). PTFs are mathematical functions or models which map the soil survey database (the domain) to the soil hydraulic properties (the co-domain), and are formulated in a nested fashion, using the scales. The goal of the hydrogeological discipline in itself is to use these PTFs and other similar methods to connect the pedon-scale measurements (micro/mesoscopic) to the landscape-scale phenomena (macroscopic) in a three-way interconnection between soil structure, preferential flow, and water quality. Similarly, transfer functions have been used in a range of temporal scales of recharge and groundwater level fluctuations as input and output, respectively, to fractured crystalline rock aquifers, to quantify the aquifer recharge. Hyperspectral remote sensing data of different spatial and temporal scales has been used to monitor vegetation at laboratory (plot), field (local), and landscape (regional) levels. Different geometric resolutions in these images provide heterogeneity of vegetation indices, where the information between scales is harmonized by using transfer functions.

Coupling across different scales to communicate information is another one of the multiscaling methods. Consider the instance of interdisciplinary study of earth sciences involving interconnections between thermal, hydrous, mechanical, and chemical (THMC) behavior of the earth (Regenauer-Lieb et al. 2013). There exists a multiphysics model of THMC coupling across different scales, in both spatial length and time, which enables communication needed for the transition between scales. As an example, for earth resource processes, the spatial scales range from nanometers to 100 kilometers and the time scales range from femtoseconds to $1e+8$ years. These are the scales involved for energy and mineral resource discovery, involving a geodynamic framework. One of the unifying concepts across scales is where the macroscale of one process is used as the microscale of a process at a higher level, thus facilitating multiscaling. Statistical mechanics and thermodynamics offer tools to solve such problems, e.g., macroscopic thermodynamic properties of a continuous medium are derived using stochastic modeling of multiple microscale interactions. The poor availability of order parameters, microscale intrinsic length scales, and energy-based interactions is a roadblock for using the concept as is. To overcome this, the larger scale entities use inputs computed using percolation renormalization at the microscopic scale through coarse graining, and an asymptotic homogenization at the macroscopic scale. Percolation theory has been conventionally used for determining global behavior, e.g., phase transitions, in a random heterogeneous system, e.g., randomly structured media.

It is widely known that earth observations and analysis are sensitive to the scale of data acquisition (Zhao 2001). Thus, an important application of object detection in very-high-resolution imagery entails estimation of scale parameters at different resolutions to segment the images appropriately. Segmentation provides the geometric representation of the spatial objects present in the region captured in the images. The scale parameter depends on local variance of the object heterogeneity in the scene as well as the rate of change of the local variance across consecutive scales. This is because the structural information of the region is derived from the pixel information, which encodes the object heterogeneity. This structural information is effectively obtained from the features extracted from the remotely sensed images. In addition to the hierarchical organization of scales and navigation using transfer functions, scale-space filtering is a commonly used method in feature extraction using multiscaling (Lindeberg 1998). The scale-space theory states that the smaller-scale structures disappear sooner than the larger-scale ones, when the scale-space representation is defined using smoothing. The smoothing is done using Gaussian or wavelet filters. The smaller-scale structures are also perceived as noise, thus, using the scale-space representation for denoising images or filtering noise from the images. This also works

on the principle of *persistence* of *significant features* across multiple scales. An example application for feature extraction using multiscaling is for land cover-based image classification of Landsat images.

Case Study: Feature Extraction in LiDAR Point Clouds

Consider a deeper study on how multiscaling is used for feature extraction in point clouds acquired using airborne LiDAR or terrestrial LiDAR technology. Use of multiple scales in point cloud analysis is a well-established practice to address the uncertainty in environmental datasets. These features are further used for semantic classification, i.e., object-based classification of the point clouds. The classification is an important data analytic step in point cloud analysis. In point clouds, spatial locality is exploited using the neighborhood defined by the scale parameter. The local neighborhood itself can be determined using different approaches. The local neighborhood of each point in the point cloud has been defined in the state of the art using either the limiting shape of the neighborhood and/or the size of the neighborhood set. A neighbor of a point p is defined as a point which satisfies the distance criterion defining the local neighborhood of p . The different kinds of local neighborhoods generally used for point cloud analysis are spherical, cylindrical, cubical, and k -nearest neighborhoods. The distance used is usually the Euclidean distance or l_2 norm, and in certain applications, its limiting case of Chebyshev distance or max-norm is used. The size of the local neighborhood is, then, used as the scale parameter. For instance, the radius of the spherical or cylindrical neighborhood is the scale parameter, so is the length of side in the cubical neighborhood, and the value of k in the k -nearest neighborhoods.

Conventional workflow involves feature extraction at each scale for a set of consecutive scales, with lower and upper bounds (s_{min} and s_{max}), and the step size (Δs) of the scale parameter defined for each application. Determining the scales for effective feature extraction is in itself a difficult problem. Applications which use an optimal scale s_{opt} for the final feature vector are not as critically dependent on the choice of $[s_{min}, s_{max}, \Delta s]$ as the applications where feature vectors at all scales are used for further data processing.

Before discussing how features across different scales are aggregated meaningfully for any application, the feature extraction at each scale must be discussed. For a given point and its selected neighborhood, the local geometric descriptor is computed. A widely used local geometric descriptor is the covariance matrix or tensor, C . It is a positive semidefinite second-order tensor (Sreevalsan-Nair and Kumari 2017), computed as the sum of outer product of distance vector between the point and each of its local neighbor. Tensor

voting is an alternative for computing local geometric descriptors, as it generates positive semidefinite second-order tensor fields. The nonnegative eigenvalues of C are used as features, upon its eigenvalue decomposition. There is also a variant of C , where the distances of the neighbors are computed with respect to the centroid of the local neighborhood, instead of the concerned point itself. This is effectively equivalent to performing a principal component analysis of the local neighborhood of the point. Thus, the eigenvalue-based features essentially capture the shape of the local neighborhood. The shape of the local neighborhood in itself gives the geometric classification of the concerned point to a linear, areal/surface, or volumetric feature (Sreevalsan-Nair and Kumari 2017). The eigenvalue-based features provide a probabilistic geometric classification, as these features are scale dependent. Overall, the eigenvalue-based features of a point are essential in interpreting the point in its spatial context. For semantic classification, height-based features of the point are also significant as the eigenvalue-based ones, thus making the best optimal count of significant features to be 21. Now, consider three different ways the feature vectors across multiple scales are used.

The first method, which is a widely used method, is to determine an optimal scale where the eigenvalue-based features provide the minimum entropy (Demantké et al. 2011). The scale with lowest entropy is the scale at which the local neighborhood has the optimal shape, i.e., the local neighborhood has the least uncertainty in realizing the geometric class of the point. There is a variant of the method, where the optimal scale uses local minimum value instead of global minimum value in entropy. Overall, the method of aggregating multiple scales involves determining the optimal scale s_{opt} , and using the feature vector computed at s_{opt} . This is a conservative method, as the multiscale aggregation does not involve feature aggregation. The second method involves concatenation of multiscale features into a long vector (Hackel et al. 2016). This method is apt for both supervised learning using random forest classifiers as well as neural networks, for classification applications. The long feature vector is the most effective where locally significant features are determined and used, and is equivalent to the optimal scale method. The third method involves performing a map-reduce operation on the multiscale features. One way is to average the features, however the semantics of the features must be considered before performing the averaging operation (Sreevalsan-Nair and Kumari 2017). For instance, viewing different scales as mutually exclusive events justifies the averaging operation as the computation of the likelihood of the value of the concerned feature. The feature vectors computed using each of these three methods have been found to be effective for classification of different airborne and terrestrial laser scanned point clouds.

Future Scope

Scale selection continues to be an important problem to solve for multiscaling. One such solution, for images, uses a general methodology for spatial, temporal, and combined spatiotemporal dimensions (Lindeberg 2018). Most often, the scale selection in image processing and computer vision is applied sparsely in regions of interest (ROIs). The solution of the general methodology, on the contrary, performs dense scale selection where local extrema, such as minimum entropy, are computed at all points in the image and at all time instances. However, using mechanisms involving local extrema poses a problem of the strong dependency on the local order used for finding the locally dominant differential structure. This problem of phase dependency of local scales can be reduced by performing either post-smoothing or local phase compensation.

Machine learning (ML) methods have been applied to several problems in solid Earth geosciences (sEg), but with limited impact, owing to the limitations in data quality. Various physical systems seen in sEg are complex and nonlinear, implying that the data they generate are complex, with multiresolution structures in both space and time, e.g., fluid injection and earthquakes are strongly nonstationary (Bergen et al. 2019). Hence, the need of the hour is to generate more annotated data using multiscaling, which can model multiresolution data effectively. This can remove biases in frequent or well-characterized phenomena, thus improving the effectiveness of ML algorithms, especially those that rely on training datasets.

Altogether, using these illustrative examples, multiscaling can be seen as a powerful tool that has been successfully used in several geoscientific applications, with an equally large scope for influencing future applications.

Definition

Multivariate analysis refers to a collection of different methods and techniques which allow studying the relationships characterizing data sets concerning two or more variables of the phenomenon of interest. These techniques are usually applied in the stage of exploratory data analysis, with the object to identify a reduced number of variables/factors which adequately describes the main characteristics shown by the data.

Multivariate Analysis in Geosciences

In several studies of environmental sciences, the phenomenon of interest is often the result of the simultaneous interaction of different variables observed at some locations of the survey area. In this case, the available data present a *multivariate spatial structure*, and the study is usually conducted on both (a) the spatial correlation which characterizes each observed variable and (b) the relationships existing among the variables. The first aspect is directly connected to the spatial structure of the data (spatially closer locations have often similar values compared to observations recorded at more distant locations), while the second aspect is related not only to the spatial features, but also to the nature of the phenomenon and the physical-chemical characteristics that link the variables to each other.

Often in the study of natural phenomena, such as climatic and atmospheric conditions in meteorology, or the concentrations of pollutants in environmental sciences, the variables of interest are observed at different points of the survey area for several instants of time. In this case, the data set presents a *multivariate space-time structure*, and the analyses must consider jointly the space-time correlation which characterizes each variable, as well as the relationships existing among the variables.

In geosciences, large data sets of multiple variables measured at several spatial or spatiotemporal points of the study area can be analyzed by using (a) the classical multivariate statistical techniques or (b) the multivariate geostatistical tools. Evidently, the research objectives are different even if complementary. Indeed, techniques of type (a) are usually applied in the stage of exploratory data analysis and most frequently as data reduction techniques; on the other hand, geostatistical tools are used with the aim of properly defining a model for the spatial/spatiotemporal multivariate correlation shown by the data and predicting the variables at unobserved points of the domain.

It is worth pointing out that often in geosciences compositional data arises, which is multivariate data and consists of vectors of positive components subject to a unit-sum constraint (Aitchison 1982). In such a context, the use of traditional multivariate analysis, which have been developed for unconstrained data, is not suitable. Because of the properties of compositional data (Aitchison 1994), it is necessary to work in terms of the corresponding log-ratio vectors and consequently to apply compositional data analysis in a log-ratio space.

Multivariate Statistical Techniques

The traditional multivariate statistical techniques, widely used for applications in social sciences, are usually applied in the stage of exploratory data analysis. A non-exhaustive list of multivariate techniques includes:

- Principal component analysis (PCA), which linearly transforms the observed variables into few uncorrelated variables which maximizing the data variability
- Canonical correlation analysis (CCA) that studies the relationships between two groups of variables representing different attributes of the same phenomenon
- Correspondence analysis (CorA), which is usually applied for studying the association between categorical variables, representing the variable's categories in a low-dimensional space
- Cluster analysis (CA) that tries to identify homogeneous groups of observations such that the dissimilarity among groups is remarkable

- Discriminant analysis (DA), which allows the identification of a linear combination of the observed variables that best separates two or more classes of observed data

Among these techniques, PCA is one of the most used because of its fast time of processing (from a computational point of view), as well as for the simplicity of results interpretation. Moreover, interesting insights into the variables' exploration come from the results obtained through the CCA. The fundamentals of the above mentioned techniques of classical multivariate analysis are reported in the next sections.

Main Aspects of PCA

PCA is typically a technique for data dimensionality reduction: PCA transforms (linearly) several correlated variables into few unrelated variables which maximize the variance characterizing the data (Hotelling 1933; Lebart et al. 1984; Jobson 1992; Jolliffe 2002).

PCA can be used also to understand possible relationships between variables, as well as to pre-process the data and eliminating redundancy caused by variables' correlation, before variographical analysis and modeling.

It is worth highlighting that in the PCA's applications the data are considered apart from the spatial or spatiotemporal points in which they are collected. In this context, the sample points represent the *cases*.

Let $\mathbf{X}$ be the $(N \times r)$ data matrix with N observations recorded for r variables (obviously, r is much greater than 2). In other words, the columns of $\mathbf{X}$ refer to the variables under study, while the rows of $\mathbf{X}$ refer to the measurements of the variables at the spatial or spatiotemporal points.

Through the PCA, the data matrix $\mathbf{X}$ is linearly transformed into an $(N \times r)$ matrix $\mathbf{Y}$, as follows:

$$\mathbf{Y} = \mathbf{X}\mathbf{Q},$$

where $\mathbf{Y}$, usually called *score matrix*, contains r orthogonal and zero mean components, while $\mathbf{Q}$, called *loading matrix*, is the $(r \times r)$ matrix of the eigenvectors of the following variance-covariance matrix

$$\mathbf{\Sigma} = \frac{1}{N}(\mathbf{X} - \mathbf{M})(\mathbf{X} - \mathbf{M})^T, \quad (1)$$

where the $(N \times r)$ matrix $\mathbf{M}$ is the matrix of the variables' mean values. Matrix $\mathbf{Q}$ is determined such that its first column represents the direction with the maximum variance in the data, while the second column of $\mathbf{Q}$ represents the direction of the next largest variance and so on.

Hence, PCA corresponds simply to the following eigenvalue analysis of the variance-covariance matrix $\mathbf{\Sigma}$

$$\mathbf{\Sigma} = \mathbf{Q}\mathbf{\Psi}\mathbf{Q}^T, \text{ with } \mathbf{Q}^T\mathbf{Q} = \mathbf{I},$$

where $\mathbf{\Psi}$ is the diagonal eigenvalues matrix of $\mathbf{\Sigma}$.

Moreover, as $\mathbf{\Sigma}$ is a positive semi-definite matrix, its eigenvalues are all non-negative; thus by arranging the eigenvalues in descending order, it is possible to select those components which correspond to the greatest eigenvalues; these components are named *principals* since they explain most of the total variance in the observed data. Therefore, if $r' < r$ is the number of the chosen principal components which correspond to the highest eigenvalues, then the data matrix $\mathbf{X}$ is adequately approximated as follows

$$\mathbf{X} \cong \tilde{\mathbf{Y}}\tilde{\mathbf{Q}}^T,$$

where $\tilde{\mathbf{Y}}$ is the $(N \times r')$ matrix of r' selected components and $\tilde{\mathbf{Q}}$ is the $(r \times r')$ matrix of the corresponding eigenvectors.

Note that the variance-covariance matrix $\mathbf{\Sigma}$ in (1) can be used if the variables under study are expressed with the same measurement units; otherwise, when the measurement units of the variables differ in size and type, the observed variables need first to be standardized, and successively the standardized variables are used for the computation of the correlation matrix which is scale-independent.

An interesting application of PCA on a multivariate environmental data set is in De Iaco et al. (2002).

Main Aspects of CCA

CCA is a classic multivariate statistical technique that studies the relationships between two groups of variables, which represent different attributes of the same phenomenon, for example, air pollutants and atmospheric variables, or concentrations of minerals and soil geologic features.

By performing CCA it is possible to identify pairs of factors relating to the two groups of variables under study, among which the correlation is maximum (Lebart et al. 1984; Jobson 1992).

Given the $(N \times r)$ data matrix $\mathbf{X}$ with N measurements (matrix rows) for the r variables (matrix columns) under study, the following matrix

$$\bar{\mathbf{X}} = \mathbf{X} - \mathbf{M}$$

is considered for the CCA, where $\mathbf{M}$ is the matrix of the variables' mean values.

According to the main features of the analyzed phenomenon, it is possible to define two different groups of, respectively, r_1 and r_2 variables, with $r_1 + r_2 = r$. Consequently, $\bar{\mathbf{X}}$ can be obtained through the horizontal concatenation of two matrices: the $(N \times r_1)$ matrix $\bar{\mathbf{X}}_1$ and $(N \times r_2)$ matrix $\bar{\mathbf{X}}_2$. In this way, the r columns of $\bar{\mathbf{X}}$ correspond to r_1 columns of $\bar{\mathbf{X}}_1$ plus r_2 columns of $\bar{\mathbf{X}}_2$, i.e.

$$\bar{\mathbf{X}} = [\bar{\mathbf{X}}_1 | \bar{\mathbf{X}}_2]$$

Given the following variance-covariance matrix for $\bar{\mathbf{X}}$

$$\Sigma = \frac{1}{N} (\bar{\mathbf{X}}^T \bar{\mathbf{X}}) = \frac{1}{N} [\bar{\mathbf{X}}_1 | \bar{\mathbf{X}}_2]^T [\bar{\mathbf{X}}_1 | \bar{\mathbf{X}}_2] = \begin{pmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{pmatrix}$$

where

- Σ_{11} is the $(r_1 \times r_1)$ covariance matrix for the variables of the first group.
- Σ_{22} is the $(r_2 \times r_2)$ covariance matrix for the variables of the second group.
- Σ_{12} and Σ_{21} are, respectively, the $(r_1 \times r_2)$ and $(r_2 \times r_1)$ matrices of the covariances between the variables of the two groups, under the condition that $\Sigma_{12}^T = \Sigma_{21}$.

The CCA is applied in order to identify the matrices $\mathbf{A}_1$ and $\mathbf{A}_2$ which maximize the correlation between

$$\mathbf{Y}_1 = \bar{\mathbf{X}}_1 \mathbf{A}_1 \quad \text{and} \quad \mathbf{Y}_2 = \bar{\mathbf{X}}_2 \mathbf{A}_2.$$

Note that the linear combination $\mathbf{Y}_1$ and $\mathbf{Y}_2$ represent the *canonical variates*, while $\mathbf{A}_1$ and $\mathbf{A}_2$ the canonical weights.

The canonical correlation coefficient given by

$$\rho_{(\mathbf{Y}_1, \mathbf{Y}_2)} = \frac{\mathbf{A}_1^T \Sigma_{12} \mathbf{A}_2}{\sqrt{(\mathbf{A}_1^T \Sigma_{11} \mathbf{A}_1)(\mathbf{A}_2^T \Sigma_{22} \mathbf{A}_2)}}, \quad (2)$$

measures the correlation between $\mathbf{Y}_1$ and $\mathbf{Y}_2$.

Hence, finding $\mathbf{A}_1$ and $\mathbf{A}_2$ such that the coefficient (2) is maximum corresponds to solving the following problem:

$$\max_{(\mathbf{A}_1, \mathbf{A}_2)} \mathbf{A}_1^T \Sigma_{12} \mathbf{A}_2,$$

under the condition that

$$\mathbf{A}_1^T \Sigma_{11} \mathbf{A}_1 = \mathbf{A}_2^T \Sigma_{22} \mathbf{A}_2 = \mathbf{1}.$$

Finally, the inspection of the magnitudes and signs of $\mathbf{A}_1$ and $\mathbf{A}_2$ allows the analyst to detect those variables which maximize the correlation, as well as to have insights into the contrasts among the variables under study.

A very interesting application of CCA on a multivariate environmental data set is in De Iaco (2011).

Main Aspects of CorA

The theory of CorA is discussed in several books (Benzécri 1983; Lebart et al. 1984; Greenacre 1989); therefore, the main characteristics of this multivariate technique will be reviewed.

Let $\mathbf{X}$ be the observed $(l \times p)$ two-way contingency table, where each entry x_{ji} represents the joint absolute frequency associated to the j -th and i -th attributes of two categorical variables, with $j = 1, \dots, l$, and $i = 1, \dots, p$.

By performing CorA, the best simultaneous representation of the rows and columns of $\mathbf{X}$ is determined in a low-dimensional space.

Let

$$\mathbf{D}_l = \text{diag}[f_{j\cdot}] \quad (3)$$

and

$$\mathbf{D}_p = \text{diag}[f_{\cdot i}], \quad (4)$$

be two diagonal matrices of the marginal relative frequencies computed as follows

$$f_{\cdot j} = \sum_{i=1}^p f_{ji}, \quad j = 1, \dots, l, \quad (5)$$

and

$$f_{j\cdot} = \sum_{i=1}^p f_{ji}, \quad i = 1, \dots, p, \quad (6)$$

where

$$f_{ji} = \frac{x_{ji}}{\sum_{j=1}^l \sum_{i=1}^p x_{ji}}, \quad j = 1, \dots, l, \quad i = 1, \dots, p. \quad (7)$$

Through CorA, a vector $\mathbf{u}$, which maximizes

$$\mathbf{u}^T [\mathbf{D}_l^{-1} \mathbf{F} \mathbf{D}_p^{-1}]^T \mathbf{D}_l [\mathbf{D}_l^{-1} \mathbf{F} \mathbf{D}_p^{-1}] \mathbf{u}, \quad (8)$$

under the following constraint

$$\mathbf{u}^T \mathbf{D}_p^{-1} \mathbf{u} = \mathbf{1}, \quad (9)$$

is finding in a p -dimensional space.

In the same way, through CorA a vector $\mathbf{v}$ which maximizes

$$\mathbf{v}^T [\mathbf{D}_p^{-1} \mathbf{F}^T \mathbf{D}_l^{-1}]^T \mathbf{D}_p [\mathbf{D}_p^{-1} \mathbf{F}^T \mathbf{D}_l^{-1}] \mathbf{v}, \quad (10)$$

under the constraint that

$$\mathbf{v}^T \mathbf{D}_l^{-1} \mathbf{v} = \mathbf{1}, \quad (11)$$

is determined in an l -dimensional space. The following factors

$$\Phi = \mathbf{D}_p^{-1} \mathbf{u} \text{ and } \Psi = \mathbf{D}_l^{-1} \mathbf{v}$$

define the plane where the rows and columns of $\mathbf{X}$ are projected. CorA diagram (*biplot*) allows the user to find latent relationships among the categories of the observed variables (Lebart et al. 1984).

An interesting application of CorA on a spatiotemporal environmental data set can be found in Palma (2015).

Main Aspects of CA

CA is a technique of multivariate analysis used for grouping a set of variables in such a way that variables which are “similar” to each other belong to the same group (called *cluster*), while variables which are “not similar” belong to different groups. The concept of similarity is in the sense that variables which present characteristics homogeneous within each group and different from those of the variables belonging to other groups can be considered similar (Everitt 1974).

This goal can be achieved by various algorithms which deeply differ in the way the final clusters are identified. In the literature, several clustering algorithms have been developed which can be classified in *hierarchical* and *not hierarchical* or *partitionial* clustering algorithms.

Hierarchical clustering techniques generate the well-known *dendrogram* (from the Greek words “dendro” which means tree and “gramma” drawing), i.e., a particular tree diagram which shows the clustering sequences. These methods of clustering can be:

- (a) *Divisive*, if it starts from a single cluster and step-by-step splits the cluster(s) until each cluster consists of a single variable
- (b) *Agglomerative*, if it starts with so many clusters as the observed variables, then step-by-step the most similar clusters are merged together until all the variables are assigned to a single cluster.

On the other hand, not hierarchical clustering approaches divide the data set into a user selected number of clusters, minimizing certain optimization criteria (e.g., a square error function). Therefore these techniques are based on iterative algorithms which find the optimum number of clusters when a specific stopping criteria is satisfied (i.e., a maximum number of iterations fixed by the user).

In Zhou et al. (2018), a good application of CA on geochemical data is discussed.

Main Aspects of DA

DA, introduced by Fisher (Fisher 1936) to classify some fossil remains as monkeys or humanoids, is a very useful technique of multivariate analysis. In particular, this technique allows the definition of a linear combination of the observed variables which best separates two or more classes of cases. By applying DA on a multivariate data set, a model (called *discriminant function*) for the classification of the cases under study is defined.

Unlike CA, this method starts from a known classification of the cases under study; successively, by defining a latent discriminant function which synthesizes the explanatory (quantitative) variables, new cases can be assigned to one of the groups of the primary (qualitative) variable. Hence, DA can be applied for descriptive aims, namely, to classify cases, as well as for prediction purposes, namely, to assign a new case to a specific group.

Let's consider a $(N \times r)$ matrix $\mathbf{X}$ of $r \geq 2$ variables observed on N sample cases. Moreover, let's assume that the cases under study belong to K mutually exclusive groups defined by K different attributes of a categorical variable. Each group is composed by N_k cases, such that $\sum_{k=1}^K N_k = N$.

By applying DA on matrix $\mathbf{X}$, a linear combination

$$\mathbf{Y} = \mathbf{A}^T \mathbf{X}$$

of the r variables is obtained, such that the K groups are best separated. In other words, among all the linear combinations of the observed variables, DA allows the identification of those linear combinations characterized by the maximum between groups variance (in this way the difference between groups are maximized) and the minimum within-group variance (in this way the spread within the groups are minimized).

Hence, the ratio of the between-group variance on the within-group variance has to be maximized with respect to the vector $\mathbf{A}$.

The function which maximizes this ratio is called *first discriminant function*. Then, the obtained function can be used for predictive purposes in order to assign new cases to each group.

Lonoce et al. (2018) proposed an interesting application of DA on a multivariate data set concerning archaeological measurements.

Multivariate Geostatistical Tools

In geostatistics, one of the main objectives is to estimate the variable of interest at unsampled points of the domain. For this aim, it is required a model which is able to adequately describe the spatial or spatiotemporal correlation of the variable under study. In the univariate context, techniques for

modeling and estimating spatial/spatiotemporal data are widely developed (Chilés and Delfiner 1999; Cressie 1993). Moreover, the existence in the literature of large classes of admissible correlation functions (covariances or variograms), from which selecting the most suitable function for the variable under study, greatly simplifies the modeling stage. On the other hand, in multivariate geostatistics, only few models have been proposed that can explain both the correlation which characterizes each variable (often called *direct correlation*) and the one existing between the observed variables (known as *cross-correlation*). Furthermore, there are several issues related to (a) the spatial or spatiotemporal sampling, (b) the choice of valid multivariate models, (c) the lack of automatic fitting procedures, which make modeling and estimation tasks quite complex.

In multivariate geostatistics, the concept of *regionalization*, first introduced by Matheron (1965) to highlight the close link between the observed values of one variable and the locations at which the values are measured, has been extended at the *coregionalization* concept, referring to regionalized variables which are spatially or spatiotemporally dependent on each other.

The probabilistic approach to coregionalization is based on the concept of multivariate random function (MRF) in space or space-time.

Let $\{Z_i(\mathbf{s}), \mathbf{s} \in D \subseteq \mathbb{R}^d\}$, $i = 1, \dots, r$, be r random functions (RFs) on the spatial domain D , where $\mathbf{s} = (s_1, s_2, \dots, s_d)$ are the spatial coordinates (usually $d \leq 3$).

The vector

$$\mathbf{Z}(\mathbf{s}) = [Z_1(\mathbf{s}), Z_2(\mathbf{s}), \dots, Z_r(\mathbf{s})]^T \quad (12)$$

represents a spatial MRF. Hence, the RFs $Z_i(\mathbf{s})$, $i = 1, \dots, r$, which compose the vector (12) are associated with the observed variables. In particular, the measurements $z_i(\mathbf{s})_\alpha$, $\alpha = 1, \dots, N_i$, $i = 1, \dots, r$, are considered as realizations of a spatial MRF $\mathbf{Z}$ (Fig. 1).

As already pointed out, natural phenomena are usually characterized by a space-time evolution and are the result of the joint interaction of different correlated variables. Evidently, the analysis of these processes requires the measurements of two or more variables, at some locations of the survey area and for several time points. Therefore, the data set presents a multivariate space-time structure, and the analysis of its spatiotemporal distribution can be adequately performed through space-time multivariate geostatistical techniques. In this case, the MRF definition can be extended to the spatiotemporal case. In particular, let

$$\{Z_i(\mathbf{s}, t), (\mathbf{s}, t) \in D \times T \subseteq \mathbb{R}^{d+1}\}, \quad i = 1, \dots, r,$$

Multivariate Analysis, Fig. 1 Example of a sampling scheme for two variables over a 2D spatial domain

be r spatiotemporal RFs over the domain $D \times T$ where $\mathbf{s} \in D \subseteq \mathbb{R}^d$ (usually $d \leq 3$) and $t \in T \subseteq \mathbb{R}$ is the time-point.

Hence, the vector

$$\mathbf{Z}(\mathbf{s}, t) = [Z_1(\mathbf{s}, t), \dots, Z_r(\mathbf{s}, t)]^T \quad (13)$$

represents a spatiotemporal MRF.

Given the RFs Z_i , $i = 1, \dots, r$, related to the $r \geq 2$ spatiotemporal variables under study, the measurements $z_i(\mathbf{s}, t)_\alpha$, $\alpha = 1, \dots, N_i$, $i = 1, \dots, r$, are assumed as realizations of the spatiotemporal MRF $\mathbf{Z}$ (Fig. 2).

In multivariate geostatistics, the modeling procedure is essentially based on the identification of a spatial/spatiotemporal correlation model between the components of the MRF, which is able to describe the overall behavior of the phenomenon under study. For multivariate spatial data, several models have been explored (Goovaerts 1997; Wackernagel 2003; Gelfand et al. 2004; Gneiting et al. 2010), while in the space-time domain, modeling approaches and methodologies have been discussed in Christakos (1992); Christakos et al. (2002); Fassó and Finazzi (2011); and De Iaco et al. (2019). However, both in spatial and spatiotemporal context, the *linear coregionalization model* (LCM) is still the most used model to explain the correlation among the RFs of a multivariate process. The computational flexibility which characterizes the LCM represents its main strength, despite some limitations of the model which will be pointed out later on.

Let $\mathbf{Z}(\mathbf{u}) = [Z_1(\mathbf{u}), Z_2(\mathbf{u}), \dots, Z_r(\mathbf{u})]^T$ be a vector of second-order stationary RFs in a spatial domain when $\mathbf{u} = \mathbf{s} \in D \subseteq \mathbb{R}^d$ or in a space-time domain when $\mathbf{u} = (\mathbf{s}, t) \in D \times T \subseteq \mathbb{R}^{d+1}$, with $d \leq 3$. Then, first- and second-order moments of $\mathbf{Z}$ are, respectively

Multivariate Analysis, Fig. 2 Example of spatiotemporal sampling scheme for two variables (2D spatial domain)

$$E[\mathbf{Z}(\mathbf{u})] = \mathbf{M} = [\mu_1, \dots, \mu_r]^T, \quad \forall(\mathbf{u}) \in D \times T, \quad (14)$$

where $\mu_i = E[Z_i(\mathbf{u})]$, $i = 1, \dots, r$, for all points $\mathbf{u}$ of the domain, and

$$\mathbf{C}(\mathbf{h}) = [C_{ik}(\mathbf{h})] \quad (15)$$

with, respectively, $C_{ii}(\mathbf{h}) = \text{Cov}\{Z_i(\mathbf{u}), Z_i(\mathbf{u}')\}$, the direct covariances and $C_{ik}(\mathbf{h}) = \text{Cov}\{Z_i(\mathbf{u}), Z_k(\mathbf{u}')\}$, the cross-covariances ($i \neq k$) of the r RFs of $\mathbf{Z}$; the vector $\mathbf{h}$ represents the separation vector between the points $\mathbf{u}$ and $\mathbf{u}'$; in particular $\mathbf{h} = \mathbf{h}_s$ in the spatial case where $\mathbf{u} = \mathbf{s}$ and $\mathbf{u}' = \mathbf{s}'$, while $\mathbf{h} = (\mathbf{h}_s, h_t)$ with $\mathbf{h}_s = (\mathbf{s}' - \mathbf{s})$ and $h_t = (t' - t)$ in the spatiotemporal case where $\mathbf{u} = (\mathbf{s}, t)$ and $\mathbf{u}' = (\mathbf{s}', t')$.

Given the orthogonal vectors $\mathbf{Y}_p(\mathbf{u}) = [Y_p^1(\mathbf{u}), \dots, Y_p^r(\mathbf{u})]^T$, $p = 1, \dots, P$, whose r components are second-order stationary RFs, with

$$E[Y_p^v(\mathbf{u})] = 0, \quad v = 1, \dots, r, \quad p = 1, \dots, P,$$

and

$$\text{Cov}[Y_p^v(\mathbf{u}), Y_{p'}^{v'}(\mathbf{u}')] = \begin{cases} c_p(\mathbf{h}) & \text{if } v = v', \quad p = p', \\ 0 & \text{otherwise,} \end{cases}$$

by assuming the LCM, the MRF $\mathbf{Z}$ is defined as follows

$$\mathbf{Z}(\mathbf{u}) = \sum_{p=1}^P \mathbf{A}_p \mathbf{Y}_p(\mathbf{u}) + \mathbf{M} \quad (16)$$

where $\mathbf{A}_p$, $p = 1, \dots, P$, are the $(r \times r)$ matrices of coefficients and $\mathbf{M}$ is the vector defined as in (14).

In other words, the LCM assumes that each Z_i is described through a linear combination of r orthogonal RFs Y_p^v , $v = 1, \dots, r$, $p = 1, \dots, P$, at P different variability scales. Hence, in the LCM, the matrix $\mathbf{C}(\mathbf{h})$ in (15) can be expressed as a linear combination of the basic covariance functions c_p , i.e.

$$\mathbf{C}(\mathbf{h}) = \sum_{p=1}^P \mathbf{B}_p c_p(\mathbf{h}), \quad (17)$$

where the $(r \times r)$ matrices

$$\mathbf{B}_p = \mathbf{A}_p \mathbf{A}_p^T, \quad p = 1, \dots, P,$$

must be positive-definite for the admissibility of the above model.

In spite of the computational simplicity and flexibility of the coregionalization model, both in spatial and spatiotemporal context (Wackernagel 2003; De Iaco et al. 2010, 2012), some limitations of the model need to be highlighted.

In particular, in the coregionalization model, the cross-covariance functions satisfy the following properties of symmetry:

$$C_{ik}(\mathbf{h}) = C_{ki}(\mathbf{h}), \quad (18)$$

$$C_{ik}(\mathbf{h}) = C_{ik}(-\mathbf{h}), \quad (19)$$

with $i, k = 1, \dots, r$, $i \neq k$.

Evidently, in the spatiotemporal context, $\mathbf{h} = (\mathbf{h}_s, h_t)$ and $-\mathbf{h} = (-\mathbf{h}_s, -h_t)$.

As known, in general the cross-covariance functions are not symmetric and do not satisfy conditions (18) and (19). In some applications the correlation between two variables is asymmetric with respect to the separation vector $\mathbf{h}$, therefore assuming symmetry for the cross-covariances can produce unreliable results. In this context, it could be useful the definition of covariance functions which describe the direct and cross-correlation among the variables and do not satisfy the above properties.

It is worth noting that in 1993 Grzebyk (1993) extended the LCM to the complex domain allowing the use of not-even cross-covariance functions, and more recently Li and Zhang (2011) discussed asymmetric cross-covariance functions.

In the coregionalization model, the cross-covariance functions satisfy not only the symmetry assumptions (viz., invariance with respect to the spatial or spatiotemporal separation

vector, as well as to the exchange of the variables) but also the non-separability condition. In other words, it is assumed that the cross-covariances C_{ik} , $i, k = 1, \dots, r$ are not proportional, namely, they are not described by the following intrinsic model

$$C_{ik}(\mathbf{h}) = a_{ik}\rho(\mathbf{h}),$$

where $\rho(\cdot)$ represents a correlation function, while a_{ik} , $i, k = 1, \dots, r$, represent the elements of an $(r \times r)$ matrix which is positive-definite.

Several methodologies have been developed in the literature, in order to assess symmetry and separability/non-separability conditions of the cross-covariances. Therefore, before adopting the coregionalization model to synthesize the multivariate spatial or spatiotemporal correlation among the analyzed variables, it is convenient to check if symmetry and non-separability conditions are satisfied, as thoroughly discussed in De Iaco et al. (2019) and Cappello et al. (2021).

Summary

The study of a multivariate data set concerning two or more variables of the phenomenon of interest can be done by using either classical multivariate statistical techniques mainly for exploratory purposes (detection of specific features or identification of a reduced number of hidden factors which are common to the observed variables) or multivariate geostatistical techniques to model the spatial/spatiotemporal correlation which characterizes the analyzed data.

Multivariate Data Analysis in Geosciences, Tools

John H. Schuenemeyer

Southwest Statistical Consulting, LLC, Cortez, CO, USA

Definition

Multivariate data occurs frequently in the geosciences. Graphical and statistical tools are applied to extract information from large, complex data sets. Methods are suggested for different types of problems.

Introduction

Multivariate analysis in the geosciences begins with an exploratory procedure that allows the analyst to gain a better understanding of a complex data set. Data is obtained in many ways. The preferred method would be from designed experiments, often categorized by a formal experimental design or sampling design since they yield more generalizable results. However, because of the cost of sampling (the need for ships, satellites, deep drilling), time sensitivity (floods and earthquakes), and accessibility of sites (access to land, harsh conditions), this may not be possible.

This entry discusses procedures by categories keyed to data analytic tasks. The tasks within categories include reducing the number of variables, clustering observations, gaining insight into correlation among variables, and classifying observations. Most of the variables we present are metric variables, which are variables that can be measured quantitatively. These include interval, ratio, and continuous variables.

Examples are from the geosciences, broadly defined to include energy, geology, archaeology, climate, and ecology. Procedures used to understand data obtained in these disciplines overlap. Geochemical data is common in geosciences. Often it is partly compositional data, which will be presented after a discussion of categories. Selected references are provided. A general reference with geoscience examples is by Schuenemeyer and Drew (2011).

Categories

The categories below list specific tasks that need to be addressed while performing multivariate exploratory data analysis. Under each category, one or more approaches are presented. In the section after this, alternative approaches are presented:

1. **Graphical procedures.** Graphical procedures are usually the first stage in multivariate exploratory data analysis and frequently are an extension of those used in univariate or bivariate analysis. They are used in the methods described in the following categories. Boxplots are one of the most effective ways to compare distributions of several variables expressed in the same unit. Density plots are alternatives. Using three dimensions plus color, size, and shape can extend a two-dimensional scatter plot to six dimensions. In addition, this system can be rotated. Faceting or grouping allows plotting of multiple variables on a single graph such as a histogram or boxplot.
2. **Dimensionality reduction.** Data sets in the earth sciences sometimes have dozens to hundreds of variables, partly due to the high initial cost of sampling and the relatively low marginal cost of sampling additional variables. In such cases, the variables can be highly correlated, meaning that the dimensionality of the system is less than the number of variables. This can result in interpretation, storage, and computational problems. Some approaches to transform a data set in high dimensional space to one in a lower dimensional space are:
 - (a) Principal component analysis (PCA) is an orthogonal transformation of a system of correlated variables into one of uncorrelated variables. The result is an ordered system by percent of variability accounted for by principal components $PC_1, \dots, PC_p$, where p is the number of variables. The hope is that a significant percent of the total variability will be accounted for by m variables where $m \ll p$. For example, we show (Schuenemeyer and Drew 2011) that 78% of the total variability of 21 variables from the Freeport coal bed was accounted for by seven variables.
 - (b) A second, more modern but more difficult, procedure to implement is reduction of the number of variables by machine learning. In a machine learning approach, criteria are established that variables must meet to be retained. These could include variability, distance, and passage of statistical tests.
3. **Clustering of observations by group where the variables have similar characteristics.** Cluster analysis seeks to group observations by like variables. As a result of clustering, observations in each group should be more similar than those in different groups. This reduces the number observations, as opposed to dimensional reduction of variables. Examples of cluster analysis in earth and environmental science include:
 - Identifying waste sites based on variables describing measures of toxicity.
 - Defining climate zones based on measures of pressure, precipitation, and temperature.

- Identifying archaeological sites based on the chemical composition of pottery sherds.

The number of approaches to finding clusters is too numerous to describe in this report, but here are possibilities:

- (a) Hierarchical clustering is a tree-based approach divided into two types of algorithms – agglomerative and divisive. An *agglomerative approach* begins at the lowest level, that is, each observation is a cluster. The first step upward is to combine the two observations that are closest according to some criterion, which could be as simple as medians. The path upward continues until a stopping rule or one cluster consisting of all observations is reached. The inverse of this procedure is a *divisive hierarchical approach*. It begins with all observations in a single cluster and then splits groups to achieve the most diversity.
- (b) Clustering by partitioning algorithms is another set of procedures to use. Unlike with hierarchical algorithms, the number of clusters is specified in advance, and observations can be moved from cluster to cluster until some measure of closure is achieved. The k-mean algorithm is frequently used. Other methods include fuzzy set and method clustering.
- (c) Multidimensional scaling (MDS) is a dimension reducing visualization method that may be effective when the number of dimensions can be reduced to three or fewer. The purpose is to reduce dimensionality while approximating the original distances or similarities. Dzwinel et al. (2005) illustrate its use in investigating earthquake patterns. MDS can also be used as a nonparametric alternative to factor analysis (FA) because it does not need the assumption of multivariate normality or a correlation matrix.
- (d) Correspondence analysis (CA) is similar to MDS.

There is no single best approach to clustering as it depends on the pattern in your data set such as elliptical or a snake-like curvature pattern. Achieving a satisfactory partitioning of data into clusters is largely a trial and effort procedure.

4. **Gaining insight into correlation among variables.** Factor analysis is a popular method used to perform this task. There are similarities to PCA, but there are important differences. PCA is a mathematical transformation. FA is a statistical model. In addition, the goal of FA is to find correlation structures. The goal of PCA is to maximize the variance of the new variables. FA is used as a statistical model when the number of factors is known and specified in advance. Since this is rarely the case, FA is more often an EDA method where several estimates of the number of factors are made. Typical output includes a factor loading

matrix where the columns are factors and each observation down a column represents the factor and variable. For example, in a two-factor solution, the variables Ca and SO₄ may have a high correlation with Factor 1 and low correlation with Factor 2. Conversely, variables Na and Cl may have a high correlation with Factor 2 and a low correlation with Factor 2. R-mode and Q-mode are alternative forms of factor analysis.

5. **Determining separation between known groups and/or classifying an object of unknown origin into one of two or more groups.** For example, an archaeologist has identified two nearby sites from buried samples from different time periods. Two questions arise: (1) How do we determine the spatial overlap, if any, among sites? (2) How do we determine with probability, to which site an observation of unknown origin belongs? We examine two approaches:

- (a) Discriminant analysis (DA) is a procedure used to determine separation between known groups and/or to classify an observation of unknown origin into one of two or more predefined groups. Two models are linear discriminant analysis (LDA) and quadratic discriminant analysis (QDA). The LDA is a model in which the population variance-covariance matrices are assumed to be the same for all sites. For QDA the homoscedastic assumption does not hold. In the archaeology example, the data set consists of two sites labeled K and N. The sites were identified by samples having variables Cu and Pb.
- (b) Tree-based modeling is a nonparametric alternative to LDA. Variables can be continuous, counts, or categorical. The procedure begins at the root node and splits on the variable that meets a classification rule that would make the splits at termination as pure as possible.

Automating Geoscience Analysis

Automated systems to understand large, complex data in many geological science disciplines are relatively new. They are discussed below.

1. **Structural equation modeling (SEM).** This methodology (Grace 2020) represents an approach to statistical modeling that focuses on the study of complex cause-effect hypotheses about the mechanisms operating in systems. SEM is used increasingly in ecological and environmental studies.
2. **Data mining versus machine learning.** Data mining (Bao et al. 2012) is a tool used to gain insight into data. The

- algorithms listed in the Categories section fall under the category of data mining. Even an algorithm to implement a procedure as simple as liner regression belongs to the data mining category because it yields information from a set of linear data. A slightly more complex algorithm would be one that distinguishes between linear and quadratic data. However, we typically think of data mining as yielding information from a larger and more complex data set. A distinguishing feature between data mining and machine learning is that machine learning (Korup and Stolle 2014; Srivastava et al. 2017) can teach itself from previous analyses of data. Data mining may be a procedure used by machine learning.
3. **Supervised versus unsupervised learning.** Most statistical learning processes fall into two categories, supervised and unsupervised learning (James et al. 2017). A statistical learning process is building a model where the data contains an input and an output. An example is regression where a possible set of explanatory variables is the input and the explanatory variable is the output. This is the training set. The supervised learning algorithm learns a function which can estimate output for future data. In unsupervised learning, there is only one set of data and the algorithm learns from the data. An example is clustering.

Compositional Data Analysis (CoDa)

This refers to the analysis of compositional data, also known as constant sum data (van den Boogaart and Tolosana-Delgado 2013; Pawlowsky-Glahn et al. 2015). Geochemical data occurs frequently in the geosciences. Compositional data are portions of a total. They include variables known as components that are expressed as fractions, percentages, or parts per million. This data has an induced correlation because, when there are p variables, only $p - 1$ are independent. Because of this closure, a variance matrix will always be singular, and the variables cannot be normally distributed. Therefore, standard statistical methods do not apply. Alternative approaches include performing a log-ratio transformation prior to analysis.

A Numerical Example

Data in the geosciences is often compositional; however, it is not always analyzed in that manner. We present a small, constructed example of a subset of a compositional data set consisting of three variables (Cu, Pb, and Zn) and 92 observations and four sites. A sample is shown in Table 1. Typically, there would be more compositional variables that may be of little interest to the investigator. The units here are percent but parts per million is another way to express compositional data.

The problem is to see if linear discriminant analysis (LDA) is a reasonable model to identify separation of existing sites using the three variables identified above. The two procedures we consider are (1) to use the data shown above and (2) to divide each of the three elements by their sum so that the variables in each observation sum to 1. A third procedure (not shown) would be to add a residual variable to the elements that would be the sum of the omitted variables.

Table 2 compares the prior (known) data with the LDA posterior results using the original data as the new data set in the LDA prediction algorithm.

The prior column shows the number of observations by site. The posterior row shows the allocation made by the prediction. The diagonal shows the number of correct allocations based on the maximum probability assigned to each observation and site. For this example, the sum of the diagonal is 65; however, a typical but arbitrary measure of accuracy is that the maximum probability must be at least 0.50. There are five correct assignments with probability less than 0.50. Applying this rule would yield an estimation accuracy of 0.65.

Now we examine the results obtained when the data is changed to constant sum and the compositional LDA is used. The major difference with the standard LDA is that the data argument to compositional LDA is the isometric log-ratio (ilr) transformation of the constant sum data. Following the prediction, an inverse ilr is made mapping the data back to their original units (those shown in Table 1).

Multivariate Data Analysis in Geosciences, Tools, Table 1 A subset of compositional data; units are percent

Site	Cu	Pb	Zn	Site	Cu	Pb	Zn
A	11.1	5.4	6.1	C	8.6	2.7	6.3
A	9.8	1.8	17.4	C	8.1	5.5	5.0
A	8.9	1.9	13.2	C	8.1	5.0	4.9
B	8.3	2.0	5.8	D	9.2	1.6	9.3
B	7.9	5.9	8.1	D	9.1	2.7	7.9
B	7.9	2.4	9.4	D	8.9	4.7	10.1

Multivariate Data Analysis in Geosciences, Tools, Table 2 A comparison of prior and posterior results using the untransformed data

	Site				
	A	B	C	D	Prior
A	9	2	0	3	14
B	0	24	1	5	30
C	0	5	5	5	15
D	2	3	1	27	33
Posterior	11	34	7	40	92

Multivariate Data Analysis in Geosciences, Tools, Table 3 A comparison of prior and posterior results using the ilr transformed data

	Site				
	A	B	C	D	Prior
A	7	5	1	1	14
B	2	20	2	6	30
C	0	2	10	3	15
D	1	6	3	23	33
Posterior	10	33	16	33	92

The definitions are the same as those in Table 3. However, for this example, the sum of the diagonal is 60, and there are six correct assignments with probability less than 0.50. Applying this rule would yield an accuracy of 0.59.

There are numerous reasons for differences in accuracy between the two approaches that go far beyond the scope of this report. However, it is proper to use the compositional LDA when appropriate.

Summary and Conclusion

This report presents tools for a user to gain insight into multivariate data. They are listed by category, and within each category there are brief discussions of different algorithms. Alternative tools are discussed that are useful when analyzing large complex data sets. Finally, a brief discussion of compositional data followed by an example is presented because its use in the geosciences is common and such data requires a nonstandard statistical approach to analysis.

Biography

Václav Němec is a Czech scientist born on November 2, 1929, in Prague. He has been a founding member of the International Association for Mathematical Geosciences (IAMG) since 1968 and has contributed significantly to the dissemination of scientific knowledge of mathematical geology in Eastern Europe.

He started his study of economics at the Technical University of Prague in 1948. At that time, Czechoslovakia belonged to the so-called Eastern Bloc. In 1951, because of political reasons, he was not allowed to continue with the closing fourth academic year of his studies. The following 26 months, until the end of November 1953, he spent as a miner in a special Czechoslovak army unit for politically unreliable persons. From the end of 1953 to 1990, he was working for the Czechoslovakian geological exploration of mineral deposits service. As distant education student at Charles University in Prague, he completed his studies in the Earth sciences with a diploma in applied geophysics in 1959. He received his RNDr degree in 1967 from Charles University in economic geology with a doctoral thesis on computerized modeling of three mineral deposits exploited by the cement industry in Czechoslovakia. He received a second doctoral degree (analogous to a PhD) in 1987 from the Technical University of Košice (mining sciences) and in 1994 an engineering degree from the University of Economics in Prague as restitution for the injustice received in 1951.

His scientific work was initially focused on mathematical modeling of mineral resources in the cement industry and the investigation of planetary tectonic fault systems (Němec 1970, 1988, 1992). A stay from 1969 to 1970 as visiting research fellow at the Kansas Geological Survey (USA) was dedicated to the latter topic. As Eastern Treasurer of the IAMG, he contributed substantially to mathematical geology in 1968–1980 and 1984–1996. In this role, he organized 19 international conferences on mathematical geology as part of the annual Mining Příbram Symposia. During the East-West separation of the world until 1990, these conferences served as the most important scientific interface for mathematical geology between the politically separated hemispheres.

In addition to mathematical geology, he has devoted himself to geoethics that he introduced in 1991 as a new topic for

the Mining Příbram Symposium inspired by his wife Lidmila Němcová (Němec and Němcová, 2000). He convened five symposia on this topic at the 30th and 34th IGCs and at two outreach symposia at annual meetings of the European Union of Geosciences (EGU) in Vienna (2013–2014). He lectured as invited speaker in about 20 countries on five continents and became recognized as the “Father of Geoethics.”

In recognition of his scientific achievements in mathematical geology and his service to the IAMG, he received the IAMG’s highest award in 1991 – the William Christian Krumbein Medal. He is a member of the Russian Academy of Natural Sciences since 1995 and an active member or officer of various other national and international scientific and cultural NGOs. His scientific competence, his multilingual talent, and his musicality (as a pianist) make him an extraordinary ambassador between the nations not only in science but also in the field of culture.

Neural Networks

Vladik Kreinovich

Department of Computer Science, University of Texas at El Paso, El Paso, TX, USA

Definition

A neural network is a general term for machine learning tools that emulate how neurons work in our brains.

Ideally, these tools do what we scientists are supposed to do: We feed them examples of the observed system’s behavior, and hopefully, based on these examples, the tool will predict the future behavior of similar systems. Sometimes they do predict – but in many other cases, the situation is not so simple.

The goal of this entry is to explain what these tools can and cannot do – without going into too many technical details.

How Machine Learning Can Help

What Are the Main Problems of Science and Engineering

The main objectives of science and engineering are:

- To determine the current state of the world.
- To predict the future behavior of different systems and objects.
- If it is possible to affect this behavior, to find the best way to do it.

For example, in geosciences:

- We want to find mineral deposits – oil, gas, water, etc.
- We want to be able to predict potentially dangerous activities such as earthquakes and volcanic eruptions.
- We want to find the best ways to extract minerals that would not lead to undesirable side effects such as pollution or triggered seismic activity.

Let us describe the three classes of general problems in precise terms.

To determine the current state of the world, we can use the measurement results x . Based on these measurement results, we want to describe the actual state y of the system. For example, to find the geological structure y in a certain area – e.g., the density (and/or speed of sound) values at different depths and at different locations, we can use the seismic data x , both passive (measuring seismic waves generated by actual earthquakes) and active (measuring seismic signals generated by specially set explosions or vibrations).

To predict the future state y of the system – or at least the future values y of the quantities of interest – we can use the information x about the current and past state of the system. For example, by using the accurate GPS measurements x , we can find how fast the continents drift, and thus predict their future location y .

To find the best control y , we can use all the known information x about the current state of the system. For example, based on our knowledge of the geological structure x of the area, we would like to find the parameters (e.g., pressure) y of the fracking technique that would leave the pollution below the desired level.

Sometimes We Know the Equations, Sometimes We Do Not

In some cases, we know the equations relating the available information x and the desired quantities y . In some of these cases, the relation is straightforward: For example, simple linear extrapolation formulas enable us to predict the future continent drift. In other cases, the equations are not easy to solve: For example, it is relatively easy, giving the density structure y , to describe how the seismic signals will propagate and what

signals x to expect – but to find y based on x (i.e., to solve the *inverse* problem) is often not easy.

In most cases, however, we do not know the equations relating x and y . In this, geosciences are drastically different from physics – especially fundamental physics – where the corresponding equations are usually known (they may be difficult to solve, as in predicting chemical properties of atoms and molecules from Schroedinger's equation, but they are known).

How Machine Learning Can Help: General Case

Usually, there are cases when we know both the input x and the desired output y . In other words, we know several pairs (x_i, y_i) corresponding to different situations.

Such cases are ubiquitous for prediction problems: For example, if we are trying to predict seismic activity a week ahead, then every time a week has passed, we have a pair (x_i, y_i) consisting of the measurement results x_i obtained before the passed week and the passed week's seismic activity y_i .

Such cases are ubiquitous in control problems: Every time we do something and succeed, we get a pair (x_i, y_i) consisting of the previous situation x_i and of the successful action.

Based on such pairs, machine learning tools produce an algorithm that, given the input x , provides an estimate for the desired output y . For example, for prediction problems, we can use the current values x to get some predictions of the future values y .

Producing such an algorithm usually takes time – but once the algorithm has been produced, it usually works very fast.

How Machine Learning Can Help: Case When We Know Equations

When we know equations, the difficulty is usually in solving the inverse problem – finding y based on x . In contrast, the “forward” problem – finding x based on y – is usually easy to solve. So, what we can do is select several realistic examples $y_1, \dots, y_n$ of y , compute the corresponding x 's $x_1, \dots, x_n$, and feed the resulting pairs $(x_1, y_1), \dots, (x_n, y_n)$ into a machine learning tool.

As a result, we get an algorithm that, given x , produces y – i.e., that solves the inverse problem.

Limitations

There Are Limitations

So far, it may have seemed that machine learning is a panacea that can solve almost all of our problems. But, of course, the reality is not always rosy. To effectively use machine learning, we need to solve three major problems:

- First, the ability of machine learning tools to process multi-D data is limited. In most cases, these tools cannot use *all* the measurement results that form the input x_i and the output y_i . So, we need to come up with a small number of informative characteristics. This selection is up to us, it is difficult, and if we do not select these characteristics correctly, we lose information – and the machine learning program will not be able to learn anything.
- Second, to make accurate predictions, we need to have a large number of pairs: thousands, sometimes millions. Sometimes we have many such pairs – e.g., when we are solving an inverse problem. But in many other important cases – e.g., in predicting volcanic eruptions or strong earthquakes – there are – thankfully – simply not that many such events. Of course, we can add to the days of observed eruptions days when nothing happened, but then the machine learning program will simply always predict “no eruption” – and be accurate in the spectacular 99.99% of the cases!
- Third, training a machine learning program requires a lot of time, so much that often it can only be done on a high-performance computer.

The need to solve these three problems – especially the first two – severely limits the usefulness of machine learning tools.

Let us explain, on a qualitative level, where these problems come from.

Machine Learning Is, in Effect, a Nonlinear Regression

Machine learning is not magic. It is, in effect, a nonlinear regression: Just like linear regression enables us to find the coefficients of a linear dependence based on samples, nonlinear regression enables us to find the parameters of a nonlinear regression. For neural networks, such parameters are known as *weights*.

In many practical situations – especially in geosciences – linear models provide a very crude approximation. So, crudely speaking, in addition to parameters describing linear terms, we also need parameters describing quadratic terms, cubic terms, etc. The more parameters we use, the more accurately we can describe the actual dependence. This is similar to how we can approximate, e.g., an exponential function $\exp(x) = 1 + x + \frac{x^2}{2!} + \dots$ by the first few terms in its Taylor expansion: $\exp(x) = 1 + x + \dots + \frac{x^m}{m!}$ (this is, by the way, how computers actually compute $\exp(x)$): the more terms we use, the more accurate is the result.

We Cannot Use All the Information

And here lies the problem. The numbers of nonlinear terms drastically grow with the number of inputs. For example, if the input x consists of m values $x = (X_1, \dots, X_m)$, then to describe a

generic linear dependencies $Y = c_0 + \sum_{i=1}^m c_i \cdot X_i$, we need $m + 1$ parameters. To describe a generic quadratic dependence $Y = c_0 + \sum_{i=1}^m c_i \cdot X_i + \sum_{i=1}^m \sum_{j=1}^m c_{ij} \cdot X_i \cdot X_j$, we already need $\approx m^2$ parameters. This already leads to a problem. For example, suppose that we are processing images. Describing an image x means describing the intensity X_i at each of its pixels i . A typical image consists of about $1000 \times 1000 = 10^6$ pixels, so here we have $m \approx 10^6$. It is easy to store and process a million values, but finding 10^{12} unknown coefficients – even in the simplest case, when we have a system of 10^{12} linear equations with 10^{12} unknown – is way beyond the abilities of modern computers.

As a result, we cannot simply feed the image into a machine learning tool – and, similarly, we cannot simply feed the seismogram into this tool. We need to select a few important parameters characterizing this image (or this seismogram). And here computers are not much help, we the scientists need to do the selection. This explains the first problem.

It should be mentioned that the situation is not so bad with images. Everyone knows that images can be compressed into a much smaller size without losing much information – e.g., a small-size photo on a webpage is still quite recognizable – and modern machine learning techniques use such methods automatically. However, for seismograms, no such no-information-loss drastic compressions are known.

What About Computation Time?

The more parameters we need, the more computation time we need to find the values of these parameters. Even if the system is linear, to find the values of q parameters – i.e., to solve a system of q equations for q unknowns – we need time $\approx q^3$, at least as much as we need to multiply two $q \times q$ matrices A and B – where to compute each of q^2 elements of the product $c_{ij} = a_{i1} \cdot b_{1j} + \dots + a_{iq} \cdot b_{qj}$, we need q computational steps (and $q^2 \cdot q = q^3$).

Even if we compress the image from a million to $m = 300$ values, if we take the simplest – quadratic – terms into account, we will need $q \approx m^2 = 10^5$ variables, so we need at least $q^3 \approx 10^{15}$ computational steps. On a usual GigaHertz PC that performs 10^9 operations per second, this means 10^6 seconds – about 2 weeks. And we only took into account quadratic terms – and just like an exponential function or a sinusoid do not look like graphs of x^2 , real-life dependencies are not quadratic either. So machine learning requires a lot of computation time – often so much time that only high-performance computers can do it. This explains the third problem.

We Need a Large Number of Samples

And this is not all. The more accurately we want to predict y , the more parameters we need. How many samples do we need? Crudely speaking, each pair (x_i, y_i) with $y_i = (Y_{i1}, \dots, Y_{ir})$ provides r equations $Y_{ij} = f(X_{i1}, \dots, X_{iq})$ for determining the unknown parameters, for some small r . So, we need approximately as many samples as parameters. In the above example of $q \approx 10^5$ unknowns, we need hundreds of thousands of example – and usually, even more. This explains the second problem.

There is an additional reason why we need many pairs. The reason is that it is not enough to just train the tool, we need to test how well the trained machine learning tool works. For that purpose, the usual idea is to divide the original pairs into the training set and the testing set, train the tool on the training set only, and then test the resulted training on the training set.

How do we know that it works well? One correct prediction may be a coincidence. However, if we have several good predictions, this makes us confident that the trained model works well. So, to gain this confidence, we need a significant number of such pairs. And in many important problems, we do not have that many pairs. For example, even if a volcano has been very active, had five eruptions, there is not enough data to confirm the model.

An Additional Problem

All the above arguments assumed that once we arranged an appropriate compression, gathered millions of sample, and rented time on high-performance computer, the machine learning tool will always succeed. Unfortunately, this is not always the case.

It is known that, in general, prediction problems, inverse problems, etc. are NP-hard, which means that (unless $P = NP$, which most computer scientists believe to be impossible) no feasible algorithm is possible that would always solve these problems. In other words, any feasible algorithm – and algorithms implemented in the machine learning tools are feasible – will sometimes not work.

Good news is that computer scientists are constantly inventing new algorithms, new tools. So if you encounter such a situation, a good idea is to team up with such a researcher. Maybe his/her new algorithm will work well when the algorithms from the software package you used did not work.

This brings us to the question of what machine learning tools are available.

What Tools Are Available

Traditional neural networks used three layers of neurons. Corresponding the number of parameters was not high, so while such neural networks can be easily implemented on a usual PC, they are not very accurate. So, if you have a few samples – not enough for more accurate training – you can use traditional neural networks, and get some reasonable (but not very accurate) results.

In the latest decades, the most popular are deep neural networks that have up to several dozen layers, and thus a much larger number of adjustable parameters. Often, they lead to spectacular results and accurate predictions. However, due to the high number of parameters, deep neural networks need a large (sometimes unrealistically large) number of sample pairs. For the same reason, deep neural networks require a lot of time to train – so much that this training is rarely possible on a usual computer. So, if you have a large number of samples – and you know how to compress the original information – it is a good idea to try to use deep learning.

There are also other efficient machine learning tools, such as support vector machine (SVM) – that used to be the most efficient tool until deep learning appeared – but these tools are outside the scope of this article.

In Case You Are Curious

So how do neural networks work? An artificial neural network consists of *neurons*. Each neuron takes several inputs $v_1, \dots, v_k$ and returns an output $u = s(w_0 + w_1 \cdot v_1 + \dots + w_k \cdot v_k)$, where w_i are coefficients (“weights”) that need to be determined during training, and $s(z)$ is an appropriate non-linear function. Traditional neural networks used the so-called sigmoid functions $s(z) = 1/(1 + \exp(-z))$, while deep neural networks use the “rectified linear” function $s(z) = \max(0, z)$.

Neurons usually form layers:

- Neurons from the first layer use the measurement results (or whatever we feed them as x_i) as inputs.
- Neurons from the second layer use outputs of the first layer neurons as inputs, etc.

How are the coefficients w_i trained? In a nutshell, by using *gradient descent* – the very first optimization method that students learn in their numerical methods class. The main idea behind this method is very straightforward: to go down the mountain as fast as possible, you follow the direction in which the descent is the steepest. Neural networks use some clever algorithmic tricks that help find this steepest direction, but they *do* use gradient descent.

Readers interested in technical details are welcome to read (Goodfellow et al. 2016) – at present (2021) the main textbook on deep neural networks.

Examples of Successful Applications

Successful applications of *traditional* (three-layers) neural networks have been summarized in a widely cited book (Dowla and Rogers 1996). There have been many interesting applications since then, especially in petroleum engineering, where even a small improvement in prediction accuracy can lead to multimillion gains. The paper (Thonhauser 2015) provides a survey of such applications. For example, neural networks are efficient in classifying geological layers based on the well log (Bhatt and Helle 2002) – this is one of the cases when we have a large amount of data, sufficient to train a neural network.

Applications of *deep learning* are a rapidly growing research area. There is a large number of papers, there are surveys – e.g., (Bergen et al. 2019). However, new applications and new techniques appear all the time – this research area grows faster than surveys can catch up. Because of this fast growth, this part of the article is more fragmentary than comprehensive – we will just cite examples of typical applications.

Probably the most active application areas are processing images – e.g., satellite images. One of the main reasons why these applications of deep learning are most successful is that, as we have mentioned, for images we can apply efficient almost-no-loss compression and thus, naturally prepare the data for neural processing. A typical recent example of such an application is (Ullo et al. 2019).

One of the most interesting applications of deep learning to satellite images is the possibility to predict volcanic activities based on images produced by satellites equipped with interferometric synthetic aperture radar (InSAR) – which can detect centimeter-scale deformations of earth’s surface (Gaddes et al. 2019).

Many examples of applications are related to solving inverse problems – since, as we have mentioned, in this case, we can easily generate a large number of examples; see, e.g., (Araya-Polo et al. 2018), (Mosser et al. 2018). The use of state-of-the-art machine learning techniques for solving inverse problem has already led to interesting discoveries. For example, it turns out that, contrary to the previously assumed simplified models of seismic activity – according to which only usual (“fast”) earthquakes release the stress, a significant portion of the stress is released through slow slip and slow earthquakes; see, e.g., (Pratt 2019).

Interestingly, sometimes even for the forward problem, neural networks produce results faster than the traditional numerical techniques; see, e.g., (Moseley et al. 2018).

The papers (Magaña-Zook and Ruppert 2017) and (Linville et al. 2019) use deep learning to solve another important problem: How to distinguish earthquakes from explosions based on their seismic waves? This problem was actively developed in the past because of the need to distinguish nuclear weapons tests from earthquakes. Now, the main case study is separating small earthquakes from small explosions like quarry blasts – and in this application, there is a large number of examples, which makes neural networks very successful.

Summary

In a nutshell, neural networks are interpolation and extrapolation tools. When we have a large number (x_i, y_i) of pairs (x, y) of related tuples of quantities, machine learning techniques – such as neural networks – produce a program that, given a generic tuple x , estimates y .

In many cases, neural networks have led to successful applications in geoscience. However, neural networks are not a panacea.

For a neural network application to be successful, we really need a very large number of examples – which is not always possible in geosciences; we need to compress the data without losing information – which is also often difficult in geosciences; we usually need to spend a large amount of computation time; and we need to be patient: Sometimes these techniques work, sometimes they do not.

We hope that this entry will help geoscientists to select problems in which all these conditions are satisfied, and get great results by applying neural networks! (And do not hesitate to collaborate with computer scientists if it does not work the first time around.)

Definition

Nonlinear mapping algorithm, firstly proposed by Sammon (1969), is a nonhierarchical method of cluster analysis for geometric image dimensionality reduction (Howarth 2017). According to the algorithm, complex relationships in high-dimensional space can be transformed and demonstrated in a low-dimensional space without changing relative relationships among internal factors. Approximate images of the relationship between high-dimensional samples can be intuitively seen in the low-dimensional space that will greatly simplify the interpretation (Sammon 1969). Nonlinear mapping algorithm has been widely applied in target classification and recognition within the research fields of geology,

chemistry, and hydrology, especially for distributions and processes with nonlinearity, for examples, applications in flood forecasting, fault sealing discrimination (Smith 1980), etc. The algorithm focuses only on data without considering types and categories, and has been efficiently used in prediction of mineralization and natural disasters.

Introduction

Observational data indicative to natures of the Earth system are often multidimensional (e.g., stream sedimentary geochemical samples recording concentrations of various elements; structure data in a form of vector consisting of length, azimuth, age, strain, stress, etc.). Consequently, researchers working in the Earth sciences, especially mathematical geosciences, often needs to deal with high-dimensional data and sometimes even faces issues of information redundancy. The so-called “curse of dimensionality” is a vivid description of complicated calculation and interpretation brought by high-dimensional data. It may also lead to obstacle of analytical method, for example calculating the inner product. Dimensionality reduction is a good way to solve the problems by transforming original high-dimensional data into a low-dimensional “subspace” where the sample density is increased and distance calculation will become simpler and more convenient. Classic methods including principal component analysis (PCA) and linear discriminant analysis (Belhumeur et al. 1996) with systematic and theoretical foundation have been well practiced in various geological applications, which assume linear data structures are existed in the high-dimensional data. However, inherited from nonlinear geo-systems, relationships among geo-variables often present nonlinearity. Utilization of linear methods to investigate these geo-variables will mislead the interpretation of nonlinear geo-processes. The proposed nonlinear mapping technique proposed by Sammon (1969) has triggered a big progress in understanding the world.

Within a p -dimension space R^p , suppose N samples with P variables can be denoted by $X_i = [x_{i1}, x_{i2}, \dots, x_{ip}]$, $i = 1, 2, \dots, N$. If the N points in the R^p space are nonlinearly mapped in a lower dimensional space R^l ($l < p$): N samples will be $Y_i = [y_{i1}, y_{i2}, \dots, y_{il}]$, $i = 1, 2, \dots, N$. The distances or relations among samples should be approximate in both spaces of R^p and R^l (d_{ij} and d_{ij}^*). A critical variable E , termed as mapping errors, is defined by total sample distances in spaces of R^p and R^l ($\sum d_{ij}$ and $\sum d_{ij}^*$) to constrained the transformation:

$$E = \frac{1}{NF} \sum_{i \in j} w_{ij} (d_{ij}^* - d_{ij})^2 \quad (1)$$

where, $NF = \sum_{i < j} d_{ij}^* \sum_{i=1}^{N-1} \sum_{j=i+1}^N d_{ij}^*$ is the normalized factor and $W_{ij} = 1/d_{ij}^*$ is the weighting factor.

$$d_{ij}^* = \sqrt{\sum_{i=1}^p [x_{ki} - x_{kj}]^2} \quad (2)$$

$$d_{ij} = \sqrt{\sum_{k=1}^l [y_{ki} - y_{kj}]^2} \quad (3)$$

The dimensionality reduction implemented by nonlinear mapping algorithm applies the variable E as the weight coefficient to minimize difference between the $\sum d_{ij}$ and $\sum d_{ij}^*$. The steepest descent method can iteratively reduce the total mapping error through adjusting coordinates of points. In general, a well mapping result will be obtained with less than a hundred iterations. When the iteration results become convergent, variations of errors should not be less than the “mapping tolerance” (often set as 0.000001). A result with less mapping errors can better preserve topological structures of samples in the original space for acquiring geometric configuration of samples in the new space.

Manifold Learning and Basic Algorithms

Manifold learning method proposed by Roweis and Saul (2000) and Tenenbaum et al. (2000) has gradually become a heat point in studies of feature extraction. Manifold learning is another category of dimensionality reduction methods. Manifold is a homeomorphous space with Euclidean space at the local scale. In other words, the Euclidean distance can be used for distance measurement at the local scale. It means when the low-dimensional manifold is embedded in the high-dimensional space, although the distribution of samples in the high-dimensional space seems extremely complicated, the properties of Euclidean space still locally stand true for those samples. Thus, the dimension reduction mapping relations between the high-dimensional and the low-dimensional spaces can be easily established at the local scale. Typical algorithms include spectrum-based algorithms, isometric mapping algorithm (Tenenbaum et al. 2000), local linear embedding algorithm (Rowies et al. 2000), local tangent space alignment (Zhang 2004), kernel principal component analysis (Schölkopf et al. 1997), Laplacian feature mapping (Belkin and Niyogi 2002), Hessian feature mapping (Donoho and Grimes 2003), etc. Here will introduce three famous and popular learning methods.

Isometric Mapping Algorithm (ISOMAP)

The basic assumption of isometric mapping algorithm (Tenenbaum et al. 2000) is when the low-dimensional manifold is embedded in the high-dimensional space, estimated straight-line distances in the high-dimensional space are misleading, since the distances cannot find their equivalence in the embedded low-dimensional manifold. The fundamental thinking of the algorithm is to approximate geodesic distances among samples according to local neighborhood distance; meanwhile, based on systematical derivation of these distances, the problem of coordinates calculation in the embedded low-dimensional manifold can be changed to the issues of eigenvalues of matrices. The implementation of isometric mapping algorithm including three steps: (1) k neighbor (the first k data closest to the data point) or ε neighbor data (all data whose point distance is less than ε) of each sample in the high-dimensional spatial data set $\{x_i\}_{i=1}^N$ need to be defined and connected to construct the weighted neighborhood figure of the high-dimensional data; (2) the shortest distances between each pair of data points within the neighborhood figure are calculated, which are further defined as an approximate geodesic estimation; and (3) the multidimensional scaling algorithm is applied to reduce the dimensionality of the original data set.

The advantages of ISOMAP are obvious. With simple parameter settings, it provides a fast and globally optimal nonlinear mapping by calculating the geodesic distance, rather than the Euclidean distance between points in high-dimensional space. However, searching for the shortest distances between each sample pair is quite time-consuming when the sample volume is too large. The ISOMAP algorithm has been successfully employed in many research fields.

Local Linear Embedding Algorithm (LLE)

Local linear embedding proposed by Roweis and Saul (2000) is another nonlinear dimensionality reduction method based on the think of manifold learning. Suppose the data lies on or near a smooth nonlinear manifold of lower dimensionality, the main idea of the algorithm is to approximate global nonlinear structure with locally linear fits. During this processes, local linear relationships between original neighborhoods are maintained, and the intrinsic local geometric properties remain invariant to the local patches on the manifold. Its specific steps of LLE include:

1. Assign neighbors to each data points, for example using the k nearest neighbors.

2. Calculate the local linear reconstruction weight *matrix* W of the data from its neighbors by solving the following constraint least-square problem:

$$\varepsilon(W) = \sum_i \left| X_i - \sum_j W_{ij} X_j \right|^2 \quad (4)$$

- Then, minimize $\varepsilon(W)$ subject to (a) $\sum_j W_{ij} = 1$, and (b) $W_{ij} = 0$, if X_j is not belong to the set of neighbors of X_i .

3. Take the parameter of local linear representation as the invariant eigenvalue of high-dimensional and low-dimensional data, and calculate the unconstrained optimization problem to obtain the dimensionality reduction result Y :

$$\min_Y \phi(Y) = \sum_i \left| Y_i - \sum_j W_{ij} Y_j \right|^2 \quad (5)$$

The advantage of LLE algorithm is to effectively record the inherent geometric structure of the data by utilizing the local linear relationship. Compared to the isometric mapping algorithm, it seeks for eigenvalue solving of sparse matrix and not requires iteration, which makes it more efficient in calculation.

Rather than the geodesic distance relationship between sample points, the local linear embedding algorithm only maintains the local neighbor relationship, so it is not well descriptive of the manifold structure of data with equidistant characteristics. It should be noticed that this algorithm is more sensitive to noises since it assumes the samples are uniformly distributed.

Kernel Principal Component Analysis Algorithm (KPCA)

Geological processes often present nonlinear characteristics. As a linear algorithm, PCA has been widely used in geosciences, but it may still fail to depict nonlinear structures embraced in geo-datasets, and unable to implement dimensionality reduction of geological characteristics, effectively. As an upgrading version, KPCA proposed by Schölkopf et al. (1997) is a nonlinear form of PCA. By introducing an integral operator kernel functions, KPCA allows to map low-dimensional space to high-dimensional space via nonlinear mapping and then executes PCA in this feature space. The intuitive idea of kernel PCA is to transform linear indivisible

problems in input space to linear divisible problem in feature space.

Suppose we first map the data in an original space R^n into a new feature space F via nonlinear mapping function φ :

$$\varphi : R^n \rightarrow F \quad (6)$$

$$x \rightarrow \varphi(x).$$

The Euclidean distance in the new feature space F can be expressed as:

$$d_n(x_1y) = \sqrt{|p(x) - \rho(y)|} \\ - \sqrt{\phi(x) \cdot \rho(x) - 2\rho(x) \cdot \varphi(y) + \varphi(y) \cdot \varphi(y)} \quad (7)$$

According to the Mercer's theorem of functional analysis, the dot product in the original space can be represented by the Mercer kernel function in the new feature space F :

$$K(x, y) = (\varphi(x) \cdot \varphi(y)) \quad (8)$$

Equations (7) and (8) can be expressed as:

$$d_H(x, y) = \sqrt{K(x, x) - 2K(x, y) + K(y, y)} \quad (9)$$

Obviously, if the kernel function $K(x, y)$ is given, by which the data can be implicitly mapped to a high-dimensional feature space. Consequently, the data are linearly separable in the high-dimensional feature space. Since the inner product in the feature space is given by the kernel function, the calculation of which will no longer be confined by the dimensionality.

The kernel function plays a vital role in the kernel method. As long as the kernel function is selected, a certain mapping is then defined. The only requirement on the kernel function is that it should meet requirements of Mercer's theorem for functional analysis. It means if the kernel function is a continuous kernel of a positive integral operator, then it performs a dot product during the mapping. Commonly used kernel functions are listed as follows, and the results will be varied according to the kernel function selected.

1. Polynomial kernel function:

$$K(x, y) = (a(x \cdot y) + b)^d \quad d > 0, \text{ and } a, b \in R \quad (10)$$

2. Gaussian radial basis kernel function:

$$K(x, y) = \exp\left(-\frac{\|x - y\|^2}{2\sigma^2}\right) \sigma \in R \quad (11)$$

3. The Sigmoid function:

$$K(x, y) = \tanh(a(x \cdot y) - b) a, b \in R \quad (12)$$

In comparison with other nonlinear algorithms, kernel PCA demonstrates its specific advantages: (1) no nonlinear optimization should be considered; (2) simple as PCA, its calculation is still focusing on solving eigenvalues; and (3) the number of preserved PCs is not necessary to be determined prior to the calculation. Due to the superiority of kernel PCA in feature extraction, it has been applied in various fields, e.g., face recognition, image feature extraction, and fault detection. From its research status, KPCA with mature algorithms employed for nonlinear feature extraction has been ideally applied in many fields.

Summary or Conclusions

Nowadays, research topics relating to nonlinear mapping are still in development. Something worth to note are:

1. Nonlinear mapping algorithm applied to geological data has advantages in removal the information redundancy of high-dimensional data, intuitive expression of data distribution patterns, and statistical significance than that of linear mapping. However, attention should be paid to two-dimensional interpretation which has possibility of failure for cases in high dimensions. Therefore, delicate interpretation and discussion at multidimensions are more appropriate.
2. Almost all algorithms have both advantages and defects, due to their complicated theoretical foundations. Some of them had been further developed, but they may still not be able to interpret the nonlinear data comprehensively. Determination of neighborhood size and algorithm upgrading for reducing noise interference and enhancing robustness will be the potential focuses in the further.

Nonlinearity

Wenlei Wang¹, Jie Zhao² and Qiuming Cheng²

¹Institute of Geomechanics, Chinese Academy of Geological Sciences, Beijing, China

²China University of Geosciences (Beijing), Beijing, China

Definition

Nonlinearity is a broad term descriptive of complex natures of the Earth system. These signatures are not an artifact of models, equations, and simplified experiments but have been observed and documented in many investigations and surveys as diverse variables. Formally defined in “*Dictionary of Mathematical Geosciences*” (Howarth 2017), the concept of nonlinearity is “The possession of a nonlinear relationship between two or more variables. In some cases, this may be a theoretical assumption which has to be confirmed by experimental data. The converse is linearity.” In order to better recognize nonlinearity, the term linearity should be referred first, which denotes possession of linear or proportional relationships among variables and can create “a straight line” in Cartesian coordinates. In contrary, nonlinearity denoting disproportional relationships among variables often creates “curves” (not a straight line) in the coordinates, e.g., parabola of a quadratic function relation. However, discrimination on linearity and nonlinearity is not that simple within the context of complex systems and complexity science. Linearity as a special case of nonlinearity merely has a proportional relationship among variables that small causes (inputs) lead to small effects (outputs), while nonlinearity often displays deviation from this simple relationship. Nonlinear relationship can be varied dramatically, and its intrinsic mechanisms are governed by the nonlinear paradigm that one cause (input) can lead to more effects (outputs) and/or one effect (output) may be led by more causes (inputs). Causative factors of nonlinearity in the Earth system are often with interrelated, interacted, and intercoupling effects, by which small variation can result disproportional and even catastrophic influence on results or other variables. Many Earth scientists even stated

that the world is inherently nonlinear, and knowledge on nonlinearity and its causative mechanisms will significantly enhance our recognition to interactions among the lithosphere, hydrosphere, atmosphere, and biosphere that will consequently progress human capability of reasonable development, natural resource utilization, prediction and/or safeguard against serious geological disasters, and environment protection.

Introduction

In the community of the Earth sciences, one of significant missions is to understand natures of the Earth for better living and long-term development. The real world is a complicated system. For solving practical problems, mathematical models should be established and solved for simulating and interpreting natural phenomena in the system, respectively. Constrained by inadequate capability and means of cognition, before advent of nonlinearity, it was generally accepted that the nature could be explicated linearly by linear equations. In order to find the approximate solution to complex systems or geoprocesses, they were routinely simplified by eliding some secondary causes or decomposing into several simple subsystems. The transformation of a nonlinear problem into linear problems is termed as linearization, during which multiple linear approximation methods were often adopted as well. There is generally a parameter by which the nonlinear equation is expanded to obtain several or infinite linear equations. The approximate solution of nonlinear issues can consequently be achieved by solving these expanded linear equations.

However, the method of linear approximation is not always effective, since development of the Earth system accompanies with not only quantitative transition but also dramatic qualitative changes. It is obvious that solution or interpretation by linear approximation works effective for linear or approximately linear phenomena, but the cases with fundamental differences from linear phenomena are often powerless. As mentioned above, nonlinearity is a ubiquitous and objective attribute in the Earth system and its compositions (subsystems). In particular, diverse geological processes including plate movement, tectono-magmatic activities, earthquakes, mineralization, etc. with dramatic variations in temperature, pressure, stress, and strain are disproportionately caused and effected by complex interaction and intercoupling mechanisms. These geological (or formation) processes essentially demonstrate nonlinearity, and it is precisely because the existence of nonlinearity prevents the practical efficiency of classic mathematical methodologies.

Joint research and thinking of the Earth and nonlinear sciences have been developed for 100 years (Ghil 2019). The Earth system and its subsystems spanning wide spatial-temporal scales that generally demonstrate nonlinearity are dynamically developed and often unrepeatable,

unpredictable, and dimensionless. The Earth scientists have proposed some nonlinear ways of thinking about these nonlinear signatures. The complex Earth system pertains to geo-processes that are believed as deterministic and can be modeled with fractal and deterministic chaos (Turcotte 1997). Progressive development in theories of chaos (Lorenz 1963), fractal (Mandelbrot 1983), and dissipative structure has profound implications for simulation, predication, and interpretation of many subsystems of the Earth (Flinders and Clemens 1996; McFadden et al. 1985; Phillips 2003).

Chaos

From observations, it can be found that occurrences of numerous natural phenomena in the deterministic Earth system with nonlinearity seem stochastic. A deterministic system is governed by rules that have no randomness and nothing stochastic. The present state can determine the future state. However, the system can sometimes have aperiodic and apparently unpredictable behaviors, and its development or evolution is not simply repetitive motion to equilibrium. Chaos is a term descriptive of evolution or development with stochastic appearance in deterministic dynamic systems. The chaos theory (Lorenz 1963; Turcotte 1997) mainly analyzes evolutive characteristics of nonlinear systems that is the evolution or development process from disorder, order, to chaos with the increase of nonlinearity. It is the science to explore their causative processes and evolutions originated from nonlinear dynamic systems which are usually described by ordinary differential equation, partial differential equation, or iterative equation. Chaos possesses both ordered periodic and disordered quasi-periodic structures that manifest the inherent randomness of nonlinear dynamic systems. The chaos theory still in development currently focuses on studying the characteristics, orderliness, and evolutionary mechanism of chaotic behaviors in nonlinear dynamic systems.

Chaotic behaviors possess random appearance but are not fundamentally stochastic. During geo-processes, the evolution and development of geo-variables or components of the Earth system demonstrate both repulsion and attraction, simultaneously. The attraction causes these variables clustered in the vicinity of a collection, while the repulsion of the collection makes these variables neither too close nor separate that reach an equilibrium state. Then the repulsion may be further enhanced resulting that these variables will be attracted by other attractors. Iterations of this process constitute complex chaotic behaviors (Fig. 1). These behaviors or geo-processes are sensitive to initial conditions and small perturbations, and initial differences or causes of minor deviations tend to persist and grow over time. From the Lorenz equation (Eq. 1), even under a same initial condition, integral

curves of repeating computation will be gradually separated and become dissimilar as the computation time increases (Fig. 1). The butterfly effect is a figurative expression of this characteristic. Consequently, short-term weather condition can be predictable, but not for long-term forecast (Lorenz 1963).

$$\begin{cases} \frac{dx}{dt} = \sigma(y - x) \\ \frac{dy}{dt} = R_a x - y - xz \\ \frac{dz}{dt} = xy - bz \end{cases} \quad (1)$$

where, x , y , and z are proportional to the intensity of convection motion, the temperature difference between the ascending and descending currents, and the distortion of the vertical temperature profile from linearity, respectively; σ is Prandtl number; b is velocity damping constant; and R_a is Rayleigh number, a natural convection-related dimensionless number.

The application of chaos theory greatly expands human's horizon and thinking of recognition to nonlinearity of geo-processes (Turcotte 1997). Applying to investigate the convection caused by nonuniform heating during the raising of mantle can reveal a dynamic process from horizontal melting, multilayered convection, and turbulence (chaos) indicating that the Earth is an open thermal-dynamic system. The evolution process includes numerous nonlinear dynamic mechanisms that produce irregular (anomalous) and incoherent chaotic but stable structures. In the Earth system, many other chaotic behaviors or phenomena can be found in lithosphere evolution, mantle convection, geomorphic systems, geomagnetic reversal, etc. (Turcotte 1997).

Fractal

Many substances formed or produced in the nonlinear Earth system are often with irregular shapes (e.g., cloud, mountain, and coastline) and heterogeneously distributed quantities (e.g., element concentration, density, magnetism, etc.). Their irregular shapes different from continuously smooth curves and surfaces well described by classical differential geometry can be continuous but unsmooth or coarse with noninteger dimensions. Traditional mathematical methodologies like Euclidean geometry (e.g., 1, 2, and 3 dimensions for point, area, and cube, respectively) cannot measure these abnormal features. They were mentioned in classical mathematical literatures, but mostly treated as special and "weird" cases without delicate discussions. As progressive awareness of spatial structures (e.g., symmetry and self-similarity of crystal

Nonlinearity, Fig. 1 A structure in the chaos – when plotted in three dimension, the solutions to Lorenz equation fell onto a butterfly-shaped set of points

and crystal grown), it turns out that they may represent another geometric form of the real world.

In mathematical sense, fractal patterns or shapes (Fig. 2) can be generated by a simple iterative equation that is a recursion-based feedback system. Using the Koch curve as an example, a straight line is taken as the initial curve. It can then be reconstructed as shown in Fig. 2 that is termed as generator with $4/3$ length of the initial curve. Repeating this process for all line segments can update the curve constituted by line segments with a total length of $(4/3)^2$. Further iteration will produce a curve with an infinite length. The curve is continuous but nowhere can be differentiable (Schroeder 1991).

The fractal theory or fractal geometry proposed by Mandelbrot (1983) is to quantify objects with irregular geometry. Since the Earth substances with irregular shapes are ubiquitous in natural systems, it is so called as “geometry of nature” (Mandelbrot 1983). If a curve is equally divided into N straight-line segments with a length of r , its approximate length $L(r)$ can be evaluated by: $L(r) = Nr$. The estimated $L(r)$

will be a finite limit as the step (r) reducing to zero. For a fractal or more complex curve, the approximate length $L(r)$ will be infinite as r goes to 0; however, there is a critical exponent $D_H > 1$ which can keep the length $L(r) = Nr^{D_H}$ as finite (Schroeder 1991). The exponent D_H is called Hausdorff dimension:

$$D_H = \lim_{r \rightarrow 0} \frac{\log N}{\log(1/r)} \quad (2)$$

When the above approximation is applied to the Koch curve (Fig. 2), choosing $r = r_0/3^n$ for the n^{th} generation, the number of segments N is proportional to 4^n .

$$D_H = \frac{\log 4}{\log 3} = 1.26 \dots \quad (3)$$

The approximation between 1 and 2 well demonstrates that the Koch curve is more irregular and complicated than a smooth curve but does not cover an area ($D_H = 2$). The Hausdorff dimension which can be fraction values is called fractal dimension in fractal geometry. Patterns, forms, or structures of the Earth substances with Hausdorff dimensions

Nonlinearity, Fig. 2 A: The initial curve; B: generator for the Koch curve; C: the next stage in the construction of the Koch curve; and D: high-order approximation to the Koch curve (D). After Schroeder (1991)

greater than their Euclidian dimensions are fractal, like the above Koch curve with a $D_H = 1.26$ between Euclidian dimensions of planar surface and volume.

Moreover, fractal possesses self-similarity, and its basic structure is scale invariant (Fig. 3). It can exhibit similar patterns as changing scales (Fig. 2). Fractal geometry is the science of complex geometry with self-similar structures to investigate intrinsic mathematical laws beneath the complex surface of nature. In practice, self-similarity is often not strictly similar, but for the case that any parts possess same statistical distributions as the whole is named as statistical self-similarity. Meanwhile, fractal theory mathematically linked to chaos and other forms of nonlinearity has been used as a morphometric descriptor of many forms and patterns produced by complex nonlinear dynamics. It has been broadly applied in the Earth sciences, especially in geology and geophysics (Turcotte 1997). In addition to classic geometry, it opens up a new way to investigate complex systems in support of simulation and explanation of nonlinear geological phenomena. The early applications were mainly to discover fractal structures and measure fractal dimensions of various geological features. Nowadays, it is more focusing on

geological processes and their indicative meanings interpreted from fractal dimension and multifractal spectrum of geological phenomena and geological bodies (Cheng 2017).

Selected Case Studies

The first selected case study of nonlinearity is chaotic processes discovered in magma mingling and mixing processes (Flinders and Clemens 1996). Inspired by the forming process of mixed patterns of two or more distinctly different fluids, the inherent deterministic chaos of magma systems was investigated through the mingling and mixing of enclave magmas with host magmas. During the chaotic process, migration of adjacent enclave blobs may be arbitrary, and these enclaves will experience different evolution. Data (e.g., crystal morphology, chemical features, and isotope) collected from microgranitoid enclaves within individual felsic magmas exhibits significant variations which may discover driving effects of nonlinear dynamics on the evolution of complex magma systems. Another example is the discovery of

Nonlinearity, Fig. 3 Singularity curve calculated from global databases of igneous and detrital zircon U-Pb ages, and the predication of the crust evolution by fractal-based models. Modified from Cheng (2017)

nonlinearity in geodynamo evidenced by palaeomagnetic data (McFadden et al. 1985). From observational palaeomagnetic data, the magnetic field in the core has a substantial and usually nonlinear effect on the velocity field, and the variation of westward drift rates can be interpreted according to nonlinear effects relating to the magnetic field intensity.

The last selected case study is on the predication of the Earth evolution (Cheng 2017). As mentioned above, knowledge on nonlinearity can enhance our capability in predication and explanation. In Cheng (2017), global databases of igneous and detrital zircon U-Pb ages were utilized to investigate episodic evolution of the crust. Fractal-based methodologies were developed to analyze shapes of the age curve with scale invariant fractality and singularity of the age records. It was discovered that the age peaks follow a power law distribution, and exponents estimated from the age curve and age peaks well demonstrate an episodic evolution of the crust. The obtained descending trend (Fig. 3) may be indicative of mantle cooling. Furthermore, following the trend of mantle cooling, it was predicted that the magmatic activities may vanish in 1.45Gyr.

Summary and Conclusions

Nonlinearity inherent from the origin and evolution of the Earth system is significant. After a century of efforts on understanding nonlinearity, theories and methodologies to interpret and explain nonlinear phenomena have greatly progressed. Nowadays, we do not only discover nonlinearity from phenomenological observation but also can reveal nonlinearity from intrinsic relations of data. There are effective

methods such as chaos and fractal to study evolutionary mechanism of nonlinear behaviors and irregular shapes caused by nonlinear processes. As a fundamental scientific issue, prediction of future development or evolution of the Earth system is an important goal of mathematical geosciences. The Earth system is a giant open nonlinear system whose variation is mutual transformation among non-stationary, deterministic, and random processes. For nonlinearity at different spatial-temporal scales, applying chaos, fractal, and other methods to construct new predication theory and methodology will be the main content of future research.

Normal Distribution

Jaya Sreevalsan-Nair

Graphics-Visualization-Computing Lab, International
Institute of Information Technology Bangalore, Electronic
City, Bangalore, Karnataka, India

Definition

Normal distributions have been widely used in natural and social sciences to approximate unknown continuous distributions of observed or simulated data. Real world data is real-valued and is handled using random variables which are variables whose values depend on outcomes of random processes. It is a parametric distribution, defined by two parameters, namely, its mean μ and its standard deviation σ . It is represented as $\mathcal{N}(\mu, \sigma)$, whose probability density function is given by

$$\phi(x; \mu, \sigma) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}}, \quad -\infty < x < \infty,$$

giving the characteristic bell curve shape, as shown in Fig. 1.

Normal distribution is unimodal, i.e., it is a distribution with a unique mode, where mode ($\mathcal{N}(\mu, \sigma)$) = μ .

The standard normal distribution is a special case of $\mathcal{N}(0, 1)$, as shown in Fig. 1. A *non-standard* normal distribution can be converted to its *standard* form, using standardized values called Z-score of the random variable, given by $Z_i = \frac{X_i - \mu}{\sigma}$. Computing probabilities for different intervals of random variables is done by converting them to their z-scores and looking up probabilities of the z-scores from the Standard Normal Distribution table. Computing probabilities of such clearly defined events correspond to direct problems. Computing the value of the random variable using its probability corresponds to inverse problems, which are also solved in the case of normal distributions by using its standardized form and the lookup table.

Normal distributions are significant due to the Central Limit Theorem (CLT). For a set of independent and identically distributed (i.i.d.) random variables in real-valued data, $X_1, X_2, \dots, X_n$, each with the same mean μ and standard deviation σ , CLT states that as n grows, i.e., $n \rightarrow \infty$, the distribution of the average of the set $\bar{X}_n$ converges to the normal distribution $\mathcal{N}(\mu, \sigma^2/n)$. This implies that, for the average value, $\lim_{n \rightarrow \infty} Z_n = \sqrt{n} \cdot \left(\frac{\bar{X}_n - \mu}{\sigma} \right)$ is the limiting case of the standard normal random variable.

Overview

Gaussian distribution is another name for the normal one, as K. F. Gauss has been attributed the origin of the normal

distribution through his work in 1809 (Gauss 1963). However, the history of normal distribution dates back to the eighteenth century (Fendler and Muzaffar 2008; Kim and Shevlyakov 2008; Stigler 1986), starting out as a way to represent binomial probability. If binomial variables represent a special case of the set of random variables, where all X_i have Bernoulli distribution with a parameter p , then, for large n and moderate values of p , ($0.05 \leq p \leq 0.95$), based on CLT,

$$\text{Binomial}(n, p) \approx \mathcal{N}\left(\mu = np, \sigma = \sqrt{np(1-p)}\right).$$

In the year 1733, Abraham de Moivre had determined the normal distribution for a special case of $p = 0.5$, as a limit of a coin-tossing distribution (Pearson et al. 1926; Stigler 1986). de Moivre had provided the first treatment of the probability integral. This was improved by P-S Laplace in 1781 by generalizing for $0 < p < 1$ (Laplace 1781; Kim and Shevlyakov 2008). Gauss in 1809 popularized the derivation of the normal distribution, but not as a limiting form of the binomial distribution. He used the normal distribution to explain the distribution of errors, thus leading to the distribution becoming eponymous to him (Gauss 1963). The use of normal distribution for errors made it appropriate for modeling errors in the linear least-squares model (LS) by Gauss. Since LS is solved using a system of equations, called as normal equations, the name “normal” is associated with the distribution itself. In short, it is widely believed that Laplace, Gauss, and a few other scientists had arrived at the normal distribution through their independent work (Stigler 1986).

The study of the theory of errors played a key role in developing statistical theory and improved the applicability of normal distribution in different domains. As the applications of normal distribution shifted from scientific to societal ones, its use began to popularize the notion of the average man in 1846 by Belgian scientist, Adolphe Quetelet, as a representative of the human population. The notion of average man perpetuates the deceptive characterization of the distribution to have stable homogeneity (Fendler and Muzaffar 2008). Thus, despite its varied applications in establishing the universality of the normal distribution, its overuse has slowly led to the need of being scrupulous of its correct formulation and usage across varied applications. Normality tests, including Q-Q plot and goodness-of-fit tests, are used for determining the likelihood that the given set of observations $X_1, X_2, \dots, X_n$ form a normal distribution. There are different types of normality. The normality tests are used to determine exact normality and approximate normality in the data. Another type of normality, asymptotic normality is a property of data, especially for a large sample, where the sample means have an approximately normal distribution, conforming to the CLT, i.e., the distribution of the z-scores of the sample means, $\bar{X}$, converges to a standard normal one as $n \rightarrow \infty$. Asymptotic normality is a key property of the least squares estimators of generalized space-time autoregressive

Normal Distribution,

Fig. 1 Plots for the probability density function in normal distribution with different values for mean μ and standard deviation σ , where the red curve is the *standard normal distribution*. (Image source: an online browser-based application, Desmos, <https://www.desmos.com/calculator/0x3rpqgrx>)

(STAR) models, used widely in ecology and geology (Borovkova et al. 2008). STAR models are applied in geological applications where prior information about spatial dependence, e.g., exact site locations for observations, is available. Asymptotic normality says that the estimator converges to the unknown parameter at a very fast rate of $\frac{1}{\sqrt{n}}$, which emphasizes the quality of the estimator. STAR models and their generalized variants are used for predicting rainfall, air pollution, groundwater levels in basin models, and similar variables in geospatial models.

Apart from its role in the CLT, normal distributions are indispensable in signal processing. Following are some of the significant properties of the normal distribution (Kim and Shevlyakov 2008) related to signal processing:

1. Two normal distributions upon convolution give another normal distribution.
2. The Fourier transformation of a normal distribution is another normal one.
3. The normal distribution maximizes entropy and minimizes Fisher information.

Solving for the variational problem of maximizing Shannon entropy $H(f)$, the distribution f that would discard

information and preserve variance bounded by its expected value $\bar{\sigma}^2$, is the normal distribution.

$$\text{For } H(f) = - \int_{-\infty}^{\infty} f(x) \log(f(x)) dx, \text{ we get } f^*(x) \\ = \arg \max_{f(x)} H(f) = \mathcal{N}(0, \bar{\sigma}).$$

Similarly, the lower bound of the variance of a parameter estimator gives minimum Fisher information. The solution of the distribution that minimizes Fisher information is a normal distribution.

$$\text{For } I(f) = \int_{-\infty}^{\infty} \left(\frac{\partial \log(f(x, \theta))}{\partial \theta} \right)^2 f(x, \theta) dx, \text{ we get } f^*(x) \\ = \arg \min_{f(x)} I(f) = \mathcal{N}(0, \bar{\sigma}).$$

Related Distributions

The normal distribution belongs to the exponential family of probability distributions, which also include log-normal, von Mises, and others.

Log-normal distribution is a close relative of normal distribution in the exponential family. It is a continuous probability distribution where the logarithm of the random variable follows a normal distribution. It is also referred to as Galton's distribution, and is widely used in modeling data in engineering sciences, including others. If the observed values are strictly positive, then the log-normal distribution is preferred for modeling over the normal distribution, which accommodates both positive and negative values (Barnes et al. 2021). Its probability distribution function is given as:

$$\phi(x; \boldsymbol{\mu}, \boldsymbol{\sigma}) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{(\ln x - \mu)^2}{2\sigma^2}} \text{ for } \mu \in (-\infty, +\infty), \\ \sigma > 0, \text{ and support } x \in (0, +\infty).$$

von Mises distribution is a continuous probability distribution, that can be closely approximated as a *wrapped* or circular normal distribution. Hence, it is also referred to as the circular normal or Tikhonov distribution. Applications of von Mises distribution include any periodic phenomena, e.g., wind direction (Barnes et al. 2021). The parameters of the von Mises distribution are μ and κ , where the latter is the reciprocal parameter of dispersion and is analogous to variance σ^2 . Its probability density function, with $I_0(\kappa)$ as the modified Bessel function of order 0, is given as:

$$\phi(x; \boldsymbol{\mu}, \boldsymbol{\kappa}) = \frac{e^{\kappa \cos(x-\mu)}}{2\pi I_0(\kappa)}, \text{ where } \mu \in \mathbb{R}, \kappa > 0, \\ \text{support } x \in \text{any interval of length } 2\pi.$$

Geostatistical Applications

Normal distributions are widely used in geostatistical modeling. Two different examples, namely, Kriging and statistical parametric mapping (SPM), are explored here to understand the relevance of normal distributions in geoscientific applications.

Data gaussianity is an essential property, where the data has the propensity for normal distributions, in geo- and spatial statistical modeling and experimental data analysis. Kriging is a widely used geostatistical methodology for interpolation that relies on the prior covariances between samples that are assumed to be normally distributed. The Kriging methodology, which is a form of Bayesian inference, involves estimating the posterior distribution by combining the Gaussian prior with a Gaussian likelihood function for each of the observed variables. This posterior distribution also tends to be normal. The covariance function is used to stipulate the properties of the normal distribution. Thus, Kriging represents the variability of the data up to its second moment, i.e., covariance. Kriging has varied interdisciplinary uses in hydrogeology, mining, petroleum geosciences (for oil production), etc.

Statistical parametric mapping (SPM) also demonstrates varied uses of normal or Gaussian distributions in spatial data mining (McKenna 2018). Spatial fields are a common representation of continuous data in geoscientific and environmental applications, e.g., permeability, porosity, mineral content, reflection in satellite imagery, etc. Comparison of such fields over time or other characteristics (e.g., ensemble runs of simulations) require the generation of difference maps, in which anomalies are detected, for better data interpretation, using SPM. SPM involves analyzing each voxel in a volumetric grid or pixel in an image, using any univariate parametric test, and the results of the test statistics are assembled in an image, in the form of a map. Properties of Gaussian or normal distribution of the data in the fields drive the SPM techniques. The pixel values in the statistical parametric map are modeled using a two-dimensional normal/Gaussian distribution function. Usually, this involves transforming a map of t-statistics to that of z-scores. Once the SPM is generated for localized anomaly detection, several post-processing steps of smoothing using Gaussian filtering, reinflation of the variance, image segmentation, and hypothesis testing are implemented in sequence. SPM has been used for anomaly detection in the imagery in satellite images, in transmissivity in groundwater pumping, etc. This specific application places a large emphasis on the Gaussian distribution of the pixels in the difference maps. Given the multivariate nature of data involved in SPM, the modeling involves multi-Gaussian (MG) fields.

Future Scope

Some of the popular geostatistical methodologies, e.g., Kriging, exploit the properties of normal distribution. Hence, to improve the applicability of such a methodology, data transformation is an option. One such method is Gaussian transformation of spatial data (Varouchakis 2021), which is needed to reduce the effect of outliers, improve stationarity of the observed data, and process the data to be apt as the input for ordinary Kriging, which is widely used. Determining such transformations is challenging, as it is highly dependent on the data and its application. The use of the modified Box-Cox technique for Gaussian transformation has been successfully used to improve the normality metrics of datasets, such as detrended rainfall data, groundwater-level data, etc. Thus, this line of work opens up research on appropriate data transformation techniques to improve normality in the data and will continue to keep normal distributions highly relevant to geostatistics.

Given the uptake in the use of neural networks for data analysis, normal distributions and related distributions (e.g., log-normal, von Mises, etc.) play a crucial role in uncertainty

quantification of data via machine learning in geosciences (Barnes et al. 2021). Uncertainty can be added to any neural network regression architecture to locally predict the parameters of a user-specified probability distribution instead of just performing value prediction. Apart from using normal distributions as user-defined ones for fitting the data, uncertainty quantification also involves adding noise which follows either normal or log-normal distribution.

In summary, this article introduces the concept of normal distribution and brushes upon its relevance in geosciences.

Object Boundary Analysis

Hannes Thiergärtner

Department of Geosciences, Free University of Berlin, Berlin, Germany

Definition

A linearly ordered set of multivariate geological objects can be segmented into quasi-homogeneous subsets significantly different from directly neighbored subsets. Rodionov (1968) developed a statistical algorithm augmenting the already known heuristic cluster-analytical models to classify ordered objects and to estimate boundaries between different subsets (1. Boundaries between ordered objects). The basic algorithm is supplemented by two algorithms that classify disordered objects into quasi-homogeneous subsets (2. Boundaries between disordered objects) and rank detected boundaries according to their importance (3. Hierarchy of boundaries).

Basic Algorithm

1. *Boundaries Between Ordered Objects.* A linearly ordered set of n vectors of m quantitative attributes $x_n = \{x_{n1}, x_{n2}, \dots, x_{nm}\}$ is to be classified iteratively into two subsets h_1 covering k vectors and h_2 covering $(n-k)$ vectors ($1 \leq k \leq n-1$). The assumed boundary between h_1 and h_2 is subjected to a statistical test. The iterative procedure is starting with $k=1$ and ending with $k=(n-1)$. Mean value vectors are calculated for both subsets. Significance of a difference d between the mean value vectors is subjected to the alternative hypothesis $H_1 (d(r^2_0) \neq \{0; 0; \dots; 0\})$ and tested against the null hypothesis $H_0 (d(r^2_0) = \{0; 0; \dots; 0\})$. The test criterion is

$$v(r^2_0) = \frac{n-1}{n(n-k)k} \sum_{i=1}^m \frac{\left((n-k) \sum_{t=1}^k x_{ti} - k \sum_{t=k+1}^n x_{ti} \right)^2}{\sum_{t=1}^n x_{ti}^2 - \frac{1}{n} \left(\sum_{t=1}^n x_{ti} \right)^2} \quad (1)$$

where x_{ti} is the measured value of attribute i for object t . A statistically significant boundary between both subsets is given at a significance level α if $v(r^2_0) > \chi^2(\alpha; m)$. The value $v(r^2_0)$ is marked. The null hypothesis is accepted if $v(r^2_0) \leq \chi^2(\alpha; m)$ meaning that the assumed boundary is not statistically significant. All significant boundaries are marked by their $v(r^2_0)$ values. Finally, a series is created of 1, 2, or at most $(n-1)$ boundaries each characterized by its $v(r^2_0)$ value. In a second step, the boundary with the maximum test criterion is selected as the most important one. It subdivides the set of ordered objects into two main subsets. Steps 1 and 2 will be repeated successively for all created subsets until new subsets cannot be established.

Step 3 includes elimination of created but unnecessary boundaries which could subdivide homogeneous neighbor vectors. It is based on a homogeneity test for all obtained boundaries between neighbored subsets T_1 and T_2 which are not resulting from the last step. The null hypothesis that a generated boundary is unnecessary will be accepted if $v(T_1; T_2) \leq \chi^2(\alpha; m)$ where

$$v(T_1; T_2) = \frac{n_1 + n_2 - 1}{n_1 n_2 (n_1 + n_2)} \times \sum_{i=1}^m \frac{\left(n_1 \sum_{t \in T_2} x_{ti} - n_2 \sum_{t \in T_1} x_{ti} \right)^2}{\sum_{t \in T_1 \cup T_2} x_{ti}^2 - \frac{1}{n_1 + n_2} \left(\sum_{t \in T_1 \cup T_2} x_{ti} \right)^2} \quad (2)$$

Acceptance of the null hypothesis means that the neighboring subsets are not significantly different from each other and that their boundary was artificially resulting from the preceding iterative procedure.

2. *Boundaries Between Disordered Objects.* This is a similar approach, but it does not get prevalence because the power of the first algorithm regarding the neighborhood is not inserted into the model.

A set of n vectors for m quantitative attributes $x_n = \{x_{n1}, x_{n2}, \dots, x_{ni}, \dots, x_{nm}\}$ which do not show any spatial order is to be classified into h subsets $T_1, T_2, \dots, T_s, \dots, T_h$ with at least two objects each. The calculation starts with the determination of all $v(T_s, T_k)$ between the $\frac{h(h-1)}{2}$ pairs of objects:

$$v(T_s, T_k) = \frac{n_s + n_k - 1}{n_s n_k (n_s + n_k)} \times \sum_{i=1}^m \frac{\left(n_s \sum_{t \in T_k} x_{ti} - n_k \sum_{t \in T_s} x_{ti} \right)^2}{\sum_{t \in T_s \cup T_k} x_{ti}^2 - \frac{1}{n_s + n_k} \left(\sum_{t \in T_s \cup T_k} x_{ti} \right)^2} \quad (3)$$

where T_s and T_k are the first and second subsets with n_s and n_k objects ($n \geq 2$) respectively, and x_{ti} is the value for attribute i for object t . Next, a test for general homogeneity of all objects is conducted. General homogeneity means that there are no significant boundaries between the multivariate described objects involved. The null hypothesis

$$H_0(\text{all } [\Theta_{T_s} - \Theta_{T_k}] = \{0; 0; \dots; 0\}) \quad (4)$$

regarding all objects will be accepted if

$$\min_{s,k} v(T_s, T_k) \leq \chi^2(\alpha; m). \quad (5)$$

At least one object shows a significantly different attribute vector, and at least one boundary exists if the null hypothesis is rejected. Θ_{T_s} refers to the mean value vector of the subset T_s which includes n_s geological objects. The procedure will be continued only if the null hypothesis is rejected. In this case, subsets will be united iteratively into larger quasi-homogenous subsets. At every step, two subsets corresponding to the term $\min_{(s,k)} v(T_s, T_k)$ form a new, larger subset without internal boundary if $v \leq \chi^2(\alpha; m)$. This new subset replaces the previous subsets T_s and T_k . The number of classes is reduced by 1. The tests are continued as before until all possible combinations of subsets have been processed.

3. *Hierarchy of Boundaries.* The problem is testing whether or not significant boundaries b_i characterized by their v -values $v_i (r^2_0)$ are of equal rank. There can arise four possible situations: boundaries are equal, one boundary is greater than or less than another one, or the boundaries are not equal.

A normally distributed test criterion

$$N = \frac{v_1 - v_2}{2\sqrt{v_1 + v_2 - m}} \quad (6)$$

will be applied only if two boundaries b_1 and b_2 are in existence. The null hypothesis $H_0 (b_1 = b_2)$ is preferred if no other hypothesis is accepted; $H_1 (b_1 < b_2)$ is accepted if $N < N(\alpha)$; $H_2 (b_1 > b_2)$ is accepted if $N > N(1-\alpha)$; and $H_3 (b_1 \neq b_2)$ is accepted if $N > N(1-\frac{\alpha}{2})$.

A χ^2 -distributed test criterion

$$\chi^2 = \frac{1}{2(2y - m)} \sum_{i=1}^k (v_i - y)^2 \quad (7)$$

will be applied if g boundaries $b_1, b_2, \dots, b_g$ exist; y is the mean value of all v -values. The null hypothesis $H_0 (b_1 = b_2 = \dots = b_g = b_0)$ that all boundaries are of equal rank is to be accepted if $\chi^2 \leq \chi^2(\alpha; k-2)$. Otherwise, at least one of the boundaries can be distinguished clearly from the other ones. If this is the case, all v -values will be ordered according to their decreasing size: $y_{i1} > y_{i2} \dots > y_{ig}$. Next, boundaries between geological objects will be united within a common class of equivalent boundaries if they do not show significant differences. This procedure will be iteratively repeated until no relation $v \leq \chi^2$ can be found anymore. The end result is a hierarchical set of boundaries classified according to their range.

Applications

Examples of linearly ordered sets of multivariate geological objects are borehole profiles, profile sections, terrestrial or submarine traverses, and time series as well.

Neighboring geological objects not separated by significant boundaries constitute quasi-homogeneous classes. Each class can be described by the estimated mean value and variance of every attribute, by the number of objects included, by its spatial or temporal position and other related information.

Spatial or temporal coordinates of the geological objects are not taken into account. Equidistance of samples or observations is not necessary, but their given linear sequence must be respected. In view of the statistical test criteria belonging to the procedure, a (0;1)-standardization of all input data is recommended so that all attributes are to receive equal weight. More subtle differences between neighbored objects can be detected if more attributes are considered. An increased statistical significance level such as $\alpha = 0.10$ instead of the commonly used $\alpha = 0.05$ diminishes the theoretical χ^2 values and results in a finer subdivision of the set of linearly ordered geological objects.

The boundaries between obtained classes can be interpreted geologically. An application of the testing model “hierarchy of boundaries” is recommended for differentiation between more or less important boundaries. Boundaries of higher order may be tectonic (e.g., thrust faults) or stratigraphic discordances. Lower-order boundaries represent general changes in tectonically undisturbed sequences of sedimentary layers or in the evolving fossil content. A boundary in the chemical composition or in mineral content provides essential information if quasi-homogeneous blocks in mineral deposits should be distinguished and delineated for subsequent mining.

The model “boundaries between disordered objects” represents an extension of the basic model “boundaries between linearly ordered objects.” The principle that a spatial neighborhood of multivariate objects is necessary does not exist anymore. Quasi-homogeneous classes can be generated even between nonneighboring objects. This statistical model competes with the better-known cluster analysis methods. However, it has the advantage of forming spatially interrelated groups of objects. An application can be recommended if a number of multivariate well logs are available for an exploratory target area or for a mineral deposit. The model then results in several closed classes both within every profile and between profiles. This gives the opportunity for cross-correlation between geologically connected profiles. The subset boundaries can be interpreted as stratigraphic, fossiliferous, or lithologic ones, or as delineations between quasi-homogeneous spatial blocks within mineral deposits. Past applications in various geological projects in Germany gave good results.

Relation to Cluster Analysis and Discriminant Analysis

The segmentation of a linearly ordered set of multivariate geological objects belongs to the group of nonsupervised classification methods. It is based on a multivariate statistical comparison of means at a chosen significance level. The user cannot incorporate any other (geo)scientific information. The model developed and introduced by Rodionov respects the neighborly relations between geological objects and enables uniting neighboring objects into a common quasi-homogeneous subset even if their attribute vectors differ to some degree. Thus, it is a generalizing approach.

A subdivision of the same set of objects by cluster analysis is a heuristic model based on one of several multivariate similarity or distance measures. Cluster analysis belongs also to the class of nonsupervised classification models. The user selects a suitable measure and can influence the result using experience and preknowledge. Information about the statistical

uncertainty is not available. Every geological object will be classified into one of several resulting groups regardless of its spatial or temporal position. In this way, the ordered sequence of objects will be subdivided into numerous independent subsets or single objects. The approach is individualizing.

Models of discriminant analysis differ clearly from the preceding models. They are supervised multivariate-statistical approaches. The boundaries between geological objects are determined a priori by geoscientific facts such as lithologic, stratigraphic, or facies allocation. This approach is applied to test the multivariate differences between predetermined classes of objects according to their statistical significance. Not yet classified objects can be assigned to existing classes at a given statistical level of significance, or they result in generating new classes of geological objects.

Example

The profile of borehole Herzfelde 4/63 east of Berlin (Germany) is to be classified by its microfauna population. It shows a monotone sedimentary sequence, poor in fossils and without any index fossils (Fig. 1). The series consists of fine to medium-grained sandstone (a), ordinary sandstone (b), calcareous sandstone (c), pelitic limestone (d), clayey limestone (e), limestone breccia (f), limestone conglomerate (g), oolitic limestone (h), dolomite (i), and clayish sandstone (j). Some layers are colored (k) and the deeper limestone is pelitic (l). The sequence covers Mesozoic sediments from the Oxfordian to the Cenomanian. The series was syn-sedimentarily to postsedimentarily disturbed by halokinetic processes (Schudeck and Tessin 2015). The sparse fossil content (residues of ostracods, charophyta, echinoderms, snails, and other types of shells and fish) was determined in 94 samples (column 2 in Fig. 1).

The segmentation of this profile by microfauna components resulted in six classes (column 3 in Fig. 1) for significance level $\alpha = 0.10$. The lower class corresponds to Oxfordian and Kimmeridgian strata and is concordantly overlain by Tithonian and earliest Berriasian followed by a weathered horizon (Early Berriasian). This sequence is overlain by poorly fossiliferous Late Berriasian and Cenomanian sediments (class no. 4, possibly limited by a tectonic fault?). Above an obvious discordance, class no. 5 continues the Early Berriasian sequence which is very rich in fossils. The hanging group follows discordantly and is composed of Early Berriasian and Late Berriasian containing only a few fossils.

A reduction of the significance level to $\alpha = 0.05$ results in altogether 16 microfauna boundaries (column 4 in Fig. 1), but the entire profile is still clearly structured into coherent sections. This is important for the geological interpretation.

Object Boundary Analysis,
Fig. 1 Boundaries between
 ordered samples in a borehole
 profile

Column 5 in Fig. 1 shows the resulting preliminary stratigraphic classification of the studied Mesozoic profile.

The difference between the generalizing method “boundaries of ordered objects” and the individualizing cluster

analysis is presented in Fig. 2. The same data set was used for both approaches. The cluster-analytic result (column 3 in Fig. 2) shows nine classes similarly composed as the groups of the Rodionov algorithm. It shows partly also closed sequences

Object Boundary Analysis, Fig. 2 Comparison between generalized and individualized boundaries

of a quasi-homogeneous composition but also embedded thin layers characterized by a different fossil content. This comparison between results is suitable to recognize the difference between generalizing and individualizing methods.

Summary

Linearly ordered or not ordered sets of multivariate geological objects can be subdivided into quasi-homogeneous subsets by multivariate statistical methods developed by Rodionov (1968). The resulting boundaries can be tested for their statistical significance and can be interpreted geologically. This *generalizing* approach is distinguished from the *individualizing* cluster analysis by preferential involving neighboring objects into a common class without explicit inclusion of spatial or temporal coordinates. Application is recommended to classify borehole profiles, time series, and related ordered geoscientific objects.

Definition

Object-based image analysis (OBIA) is defined as recognizing the target objects in an image through the processes like image segmentation, image classification, evaluation, and analysis of objects. Image segmentation is the process of dividing an image into homogeneous segments by grouping

the neighboring pixels with similar characteristics like tone, texture, color, and intensity. Image classification is the process of labeling the image objects to the respective classes as they appear in the reality. Evaluation is the process of comparing the predicted object classes to the actual/true classes. The term image objects is a group of pixels with similar characteristics. A pixel is a digital number representing the spectral reflectance from a given area.

Introduction

The earth resources change dynamically over the years due to various reasons like anthropogenic activities, natural processes and other activities. The consumption of resources such as water, forest, minerals, oil, and natural gases has increased from the past years (Lillesand and Kiefer 1994). Also, the land use/land cover changes are frequent due to the reasons such as overflows, drought, cyclones, tsunamis, etc. The percentage of resource utilization by the humans has increased over the recent years (Lillesand and Kiefer 1994). Many studies were implemented scientifically to quantify the changes in the resources like forest, water, and land use/land cover changes (Richards and Jia 2006). Remote sensing is one such type of art, science, and technology of acquiring the information about the resources on the earth surface without any physical contact with the object of interest (Campbell 1987). The images/photographs of the target of interest are obtained remotely from airborne/spaceborne platforms (Richards and Jia 2006). The very first attempt of acquiring the aerial photographs were implemented by airborne platforms like parachutes, air crafts, etc. In the recent years, space-based platforms like satellites are used to acquire the information about the target of interest (Schowengerdt 2006). The information about the target of interest is remotely sensed and represented in the form of images (Jensen 2004).

In the earlier days, the images were obtained in analog format with coarse resolution (Gonzalez and Woods 2008). Identification of object of interest in the images with coarse resolution is difficult task for the manual analysis. Advancement in the sensor technology like development of charged coupled devices generated digital images with fine spatial resolution. The digital images are more informative in comparison with analog images. A digital image consists of finite set of elements called pixels/pels (Bovik 2009). Each pixel in a digital image is indicated with digital number (DN) (Gonzalez and Woods 2008). A DN of a pixel represents the average spectral reflectance sensed by the sensor in the finite area of interest. The digital image consists of digital numbers represented in rows and columns (Bovik 2009). The digital images are processed to extract the information about the area of interest using various processing techniques like image enhancement, image transformation, and image classification (Richards and Jia 2006). The required information from the digital images is acquired with the usage of automated

methods. These automated methods are mathematically implemented using statistics, probability, set theory, graph theory, etc. (Schowengerdt 2006).

The processing and analysis of images is classified as

(i) manual approach and (ii) digital approach. In the manual approach expert committee will recognize the object of interest using the image interpretation keys/elements (Lillesand and Kiefer 1994). In the digital image processing and analysis approach the objects are detected and recognized using automated methods followed by the expert committee analysis. The DNs in an image are processed using two approaches, namely (i) Pixel-based image analysis and (ii) Object-based image analysis (Jensen 2004). The contents of present entry are given as pixel-based image analysis, object-based image analysis, major applications of object-based image analysis in remote sensing, and conclusions.

Pixel-Based Image Analysis

The pixel-based image analysis approach (PBIA) is based on spectral signature of the area of interest. In the pixel-based image analysis the processing techniques are implemented at the finite level of the digital images called as pixels (Veljanovski et al. 2011). Each pixel in the image is processed to acquire the information of the area. Pixel-based classification is one of the key operations performed in PBIA. In pixel-based classification each pixel in the input image is labelled to the corresponding class using various classifiers (Johnson and Ma 2020). The input pixel is considered as a vector in the N-dimensional feature space and the pixels of same class will form a cluster in the N-dimensional feature space. In pixel-based classification approach each pixel is assigned with the class label. There exists various pixel-based classifiers for remote sensing image analysis (Blaschke et al. 2014). K-nearest neighbors classifier assigns the class label to the pixel based on the K-nearest neighbors in the Euclidean space. Minimum distance to mean classifier assigns the class label to the pixel based on the minimum difference between the pixel value and the class mean (Veljanovski et al. 2011). Maximum likelihood classifier assigns the class label to the pixel based on the class conditional probability. The output of pixel-based classification approach is the classified image/classified map. Furthermore, the classified map is analyzed by the expert for quantitative assessment of various classes present in the image (Johnson and Ma 2020).

Pixel-based image analysis approach works well with coarse resolution image where the target object area is lesser than the spatial resolution of the sensor (Blaschke et al. 2014). This approach has limitations when the input image is with finer resolution where the target object area is larger than the spatial resolution of the sensor. Motivated with this reason, object-based image analysis approach was suggested for the

digital images. The object-based image analysis (OBIA) approach works well in recognizing the object of interest in both finer and coarser resolution digital images (Johnson and Ma 2020). The example of PBIA is provided in Fig. 1 and Fig. 2. In Fig. 1, there are three categories of vegetation classes. The input image is classified using PBIA approach and the classified output image is given in Fig. 2.

Object-Based Image Analysis, Fig. 1 Input image with vegetation classes. Reprinted from (Veljanovski et al. 2011)

Object-Based Image Analysis, Fig. 2 Output image of PBIA with vegetation classes represented in three symbols (Image is reprinted from (Veljanovski et al. 2011)). The input image is given in Fig. 1

Object-Based Image Analysis

In OBIA, the image pixels are grouped based on the similarity like color, tone, texture, and intensity characters. The group of pixels are combined to generate the image objects (Jensen 2004). The image objects represent the themes like water body, trees, buildings, grounds, etc. (Richards and Jia 2006). In OBIA, the spatial and spectral characteristics of pixels are used to recognize the target objects in the image. The steps implemented in OBIA is given in Fig 3. In the first stage of OBIA, the input image is segmented to obtain the image objects. Image segmentation is the process of dividing the input image into homogeneous regions called image segments. The major image segmentation approaches are given as (i) region based approach and (ii) boundary based approach. In the region based approach, similar type of pixels are detected using the algorithms. In boundary based approach, the algorithm searches for the discontinuity in the image. The boundary based approach is implemented using the segmentation algorithms like edge detection, point detection and line detection (Bovik 2009). The image segmentation techniques are broadly classified as threshold based method, edge-based segmentation, region based segmentation, cluster based segmentation, watershed based method, and artificial neural network based segmentation (Blaschke et al. 2014). The segmented image consists of separated image objects based on shape and size characteristics.

In the second stage of OBIA, the objects in the segmented image are labeled to the respective classes by using various classification methods. The classification algorithms are categorized as (i) parametric classification and (ii) nonparametric classification (Johnson and Ma 2020). In the parametric classification, the statistical parameters like mean, median, mode,

etc. of the input pixel values are considered during the image classification. In the nonparametric classification, the classification of digital images is performed without considering the statistical parameters of the input pixel values (Veljanovski et al. 2011). The major parametric/nonparametric classifier methods include K-means, minimum distance method, maximum probability method, ISODATA, K-nearest neighbor, support vector machines, and parallel-piped method (Johnson and Ma 2020). In addition, there exists neural networks (NNs)-based classifiers such as Kohonen networks, feedforward neural networks (FNNs), recurrent NNs (RNNs), deep neural networks (DNNs), etc. The machine learning-based classifiers such as decision trees and regression trees are used to classify the image objects into respective classes. The output of image classification is a classified map with various classes of land use/land cover classes, natural resources, etc. (Blaschke et al. 2014). The processing steps of OBIA approach is given in Fig. 4. The output of OBIA approach for the input image (Fig. 1) is given in Fig. 5.

The output classified image of OBIA approach is evaluated using various indices like user's accuracy (UA), producer's accuracy (PA), overall accuracy (OA), dispersion score (DS), and kappa coefficient (KC) (Lillesand and Kiefer 1994). The performance indices are derived from confusion matrix (CM). CM is a table of actual classified output classes assigned by a model. The sum of diagonal elements of the CM divide by total number of pixels is termed as OA (Campbell 1987). The results of OBIA are correlated with the ancillary data and evaluated with the field visits by selecting the locations based on random approach (Jensen 2004). Furthermore, based on the evaluation results, the OBIA is extended to various remote sensing applications.

Object-Based Image Analysis, Fig. 3 Schematic flow diagram of OBIA. The flow diagram consists of steps like passing the input image, segmenting the input image to obtain image objects, classifying the image objects, and evaluation of accuracy

Object-Based Image Analysis, Fig. 4 Processing steps of OBIA. Reprinted from (Veljanovski et al. 2011)

Object-Based Image Analysis, Fig. 5 Output image of OBIA with detailed vegetation classes (Reprinted from (Veljanovski et al. 2011)). The input image is given in Fig. 1

Major Applications of Object-Based Image Analysis in Remote Sensing

The applications of object-based image analysis in remote sensing is broadly classified as land use/land cover classification, forest mapping, mineral mapping, coastal zone studies, crop classification, and urban studies (Blaschke et al. 2014). In land use/land cover classification, the pixels in the image are classified into corresponding land use/land cover class like builtup land, urban dense, urban sparse, scrub land, and deciduous forest (Johnson and Ma 2020). OBIA is used in the forest studies for change detection and quantitative assessment of vegetation classes. OBIA is used to detect the minor and major lineaments in the remote sensing images for mineral exploration (Veljanovski et al. 2011). In coastal zone studies the OBIA is used to study the dynamics of shore line changes. The coastal zone applications also include the change detection in the vegetation like mangroves. The crop classification in remote sensing images consists of mapping and assessment of various type of crops in high-resolution images (Blaschke et al. 2014). In the urban studies, the OBIA is used to study the dynamics of urban sprawl and change detection in the city pattern (Johnson and Ma 2020).

The applications of OBIA exists from coarse resolution to fine resolution remote sensing images (Schowengerdt 2006). The coarse resolution remote sensing images are acquired using the sensors like Linear Imaging Self-Scanner (LISS III), Linear Imaging Self Scanner (LISS II), Multispectral Scanner (MSS), Wide field sensor (WFS), Advanced Wide Field Sensor (AWIFS), etc. (Campbell 1987). The fine resolution remote sensing images are acquired from the

sensors like Optical Sensor Assembly, GeoEye Imaging System, Shortwave Infrared sensor, etc. (Jensen 2004). The coarse resolution images has 15 m to 75 m coverage of ground area and the fine resolution images have 0.5 m to 4.5 m coverage of ground area. The OBIA is efficiently applied on monochromatic, panchromatic, multispectral, and hyper-spectral remote sensing images. OBIA has produced impressive results with the images acquired from 1–350 spectral bands (Gonzalez and Woods 2008).

Conclusions

Advancement of sensor technology produced the images with good spatial resolution. OBIA approach is used for better information extraction from the fine resolution images in comparison with traditional methods. The traditional PBIA approach produces better results with coarse resolution images in comparison with fine resolution remote sensing images. PBIA considers the spectral characteristics of the object of interest during the processing of digital images. The performance of OBIA is efficient as tested with both coarse and fine resolution remote sensing images. OBIA considers the spatial and spectral characteristics of pixels during the object recognition. These advantages of OBIA provide better results in comparison with PBIA. OBIA is used in various type of remote sensing applications like land use/land cover classification, resource monitoring, urban mapping etc., where the spatial resolution of the images varies from 75 m to 0.5 m and the spectral resolution of images varies from single band to hundred bands. OBIA is used in the applications related to earth's atmosphere, earth's surface, and earth's sub-surface. In the recent years, intensive research on OBIA with machine learning is being carried by the scientific community. OBIA with machine learning concepts produced better results in various remote sensing applications. The future scope of OBIA involves the inclusion of temporal and radiometric characteristics of objects along with spatial and spectral characteristics during the processing of digital images.

U.S. Geological Survey, Geology, Energy and Minerals
Science Center, Reston, VA, USA

Fig. 1 Ricardo A. Olea, courtesy of Ricardo A. Olea, Jr.

Biography

Dr. Ricardo A. Olea received his B.Sc. degree in Mining Engineering from the University of Chile, Santiago, in 1966, and was awarded the Juan Brüggen Prize by the Instituto de Ingenieros de Minas de Chile for the best graduating Mining Engineer. Following graduation, he started his

professional career as an exploration seismologist with the National Oil Company of Chile (ENAP). Later, he pursued advanced qualifications in the United States. He received an M.Sc. degree in Computer Science from the University of Kansas in 1972 with a thesis on “Application of regionalized variable theory to automatic contouring,” and a Ph.D. from the Chemical and Petroleum Engineering Department of the University of Kansas in 1982 with a dissertation titled “Systematic approach to sampling of spatial functions.” He immigrated to the United States in 1985 to pursue a career as a research scientist with the Kansas Geological Survey in Lawrence, Kansas, where he worked until 2003. Before joining the USGS (United States Geological Survey) in 2006, where he currently works as a Research Mathematical Statistician, he had appointments with the Department of Environmental Sciences and Engineering of the School of Public Health at the University of North Carolina in Chapel Hill; the Marine Geology Section of the Baltic Research Institute of the University of Rostock, Warnemünde, Germany; and the Department of Petroleum Engineering at Stanford University.

Besides authoring and coauthoring more than 250 publications, including 4 books, in quantitative modeling in the earth sciences, energy resources, geostatistics, compositional data modeling, well log analysis, geophysics, and geohydrology, Ricardo made exceptional contributions to the profession of mathematical geosciences and the IAMG (International Association for Mathematical Geosciences). He served as the chair of IAMG Geostatistics Committee (1985–1989), and the IAMG Membership Committee (1989–1992), as IAMG Secretary-General (1992–1996), IAMG President (1996–2000), and IAMG Past-President (2000–2004). He still takes active roles in the IAMG and maintains affiliations with professional organizations. He currently serves as an Associate Editor of the Springer journal *Stochastic Environmental Research and Risk Assessment*. Ricardo was presented with the IAMG’s highest Award, the William Christian Krumbein Medal in 2004, due to his distinguished research, service to the IAMG, and service to the profession in general.

Ricardo’s achievements and professional accomplishments are many and much more than the brief summary highlighted above. As importantly, Ricardo is a very kind and modest person, despite his distinguished career, he is always keen to highlight excellence in others rather than his own. He is an influential and a well-loved mentor for many around the world. He is a great friend and an exceptional colleague to work with. Ricardo is always dependable and democratic, and he seeks a broadly based consensus before making any decisions. He always strives to learn new things and share them with his colleagues with openness. I feel privileged to have been asked to write this contribution about Ricardo in this volume.

Ontology

Torsten Hahmann

Spatial Informatics, School of Computing and Information Science, University of Maine, Orono, ME, USA

Definition

In the mathematical geosciences the term ontology denotes an information artifact that specifies a set of terms, consisting of classes of objects, their relationships and properties, and semantic relationships between them. But even in the information and computing sciences, the word “ontology” can denote vastly different kinds of artifacts, see Fig. 1 and Table 1 for examples. They differ in purpose and scope, ranging from informal conceptual ontologies to formal ontologies and from very broad to narrowly tailored to specific domains or specialized reasoning applications. They also differ in their representation formats, which vary in formality and expressivity, ranging from concept maps and term lists to structured thesauri and further to formal languages. If the semantics of terms are expressed in a formal, that is machine-interpretable, language one speaks of a “formal ontology.” Ontologies specified in less rigorous languages are referred to as conceptual ontologies or models.

Introduction

The term ontology originates from the study of the nature of being and the categorization of the things that exist in the world. This philosophical tradition – referred to by the uppercase term *Ontology* – dates back to Aristotle’s work

on metaphysics. Within computing and information sciences, the term *ontology* is used more narrowly to refer to an artifact that result from explicitly modeling a portion of the world or, in the words of Gruber and Studer, an “explicit formalization of a [shared] conceptualization” (Staab and Studer 2009). See Jakus et al. (2013) for additional historical context.

Over the last decades, ontologies of various scopes, formalities, and expressivities have emerged for a wide range of uses. The most obvious distinction between them is how they are represented, which ranges from simple term lists and graphical models to highly sophisticated logic-based languages, with the Resource Description Framework (RDF) (<https://www.w3.org/TR/rdf11-concepts/>) and RDF Schema (RDFS) (<https://www.w3.org/TR/rdf-schema/>) and the Web Ontology Language (OWL2) (<https://www.w3.org/TR/owl2-overview/>) most widely used (Staab and Studer 2009).

Regardless of their differences, all ontologies share two ingredients: (1) a set of terms – its *terminology* or *vocabulary* – and (2) a specification of how the terms are defined or related to one another as a means of specifying the terms’ semantics, that is, how to interpret them. The terms encompass *classes*, sometimes called *concepts*, and *properties*, also referred to as *relations*, *predicates*, or *roles*. Mathematically, classes can be thought of as sets (unary relations), whereas properties have arities of two or greater (Many representation formats, including RDFS and OWL2, only permit binary properties.). As an example, an ontology may include classes such as “Town,” “Well,” and “GroundwaterBody” and binary relations between classes (*object properties* in RDFS and OWL2) such as “contains,” “drawsFrom,” or “connectedTo” as well as attributes (*data properties* in RDFS, OWL2) such as “depth,” “volume,” “latitude,” and “longitude.” By relating terms to one another via generic or specific semantic relationships or via axioms, the terms’ semantics are specified. The most prevalent semantic relations are taxonomic ones (*hyponymy* and *hypernymy*) such as “is a subclass of” (short: “is-a”) and “is a subproperty of.” Other common semantic relations are *meronymy* (part of; mereology in logic) and its opposite *holonymy* as well *synonymy*, *antonymy*, and *similarity*.

The process of developing ontologies is called *ontological engineering*, for which established methodologies, such as TOVE, Methontology, On-To, DILIGENT, or NeOn, are surveyed in the entry “Ontology Engineering Methodology”, Staab and Studer (2009). Development typically is a multi-stage process from knowledge elicitation all the way to ontology verification and validation and involves both knowledge engineers and domain experts. Various tools, including competency questions, ontology design patterns (entry ► “Pattern Recognition”), and formal ontological analysis help at various stages. More recently, the emphasis of ontological

First-order logic (FOL):
$\forall x [\text{WaterWell}(x) \rightarrow \neg \text{OilWell}(x)]$
$\forall x, y [\text{drawsFrom}(x, y) \rightarrow \text{WaterWell}(x) \wedge \text{GroundWaterBody}(y)]$
$\forall x [\text{WaterWell}(x) \rightarrow \exists y [\text{drawsFrom}(x, y) \wedge \text{GroundWaterBody}(y)]]$
$\forall x [\text{HydroRockBody}(x) \wedge \forall y [\text{GroundWaterBody}(y) \wedge \text{submat}(y, x) \rightarrow \text{WellWaterBody}(y)] \rightarrow \text{WaterWell}(x)]$

engineering has shifted to maintaining and evolving existing ontologies (Kotis et al. 2020).

Types of Ontologies

To provide an overview of the broader ontology landscape, we survey it along three dimensions. The first is an ontology's purpose, that is, how it is intended to be used. The subsequent dimensions – scope and representation format – are partially correlated to the purpose (see Table 3).

Categorizing Ontologies by Purpose

Among the vastly different uses of ontologies of interest to the mathematical geosciences, five common purposes emerge: conceptual modeling, knowledge organization (including information retrieval), terminological disambiguation, standardization, and reasoning. Many ontologies, however, serve combinations or variations of these prototypical purposes.

Conceptual modeling (see Guizzardi 2010) is the process of brainstorming a domain or application in order to identify how the concepts therein relate to one another, creating *topic* or *concept maps* wherein concepts are related via unlabeled (generic) or labeled relationships. *Entity-Relationship (ER) diagrams* or *UML class diagrams* (examples in Fig. 1) – frequently used in software and database design – are more expressive yet still predominantly visual representations. Conceptual models are often integral parts of standards.

Knowledge organization and management (see also Jakus et al. 2013) encompasses various techniques to organize and help retrieve knowledge within knowledge organization systems (KOS), supporting metadata annotations, keyword-

based semantic search, and hierarchical navigation through knowledge. The utilized ontologies typically focus on classes and include formats such as *controlled vocabularies* and *glossaries* (lists of terms without definitions or relationships between them), *taxonomies* (i.e., classes organized using hypernyms), and *thesauri* (e.g., the Getty Thesaurus of Geographic Names, (<https://www.getty.edu/research/tools/vocabularies/tgn/>) which uses taxonomic relations and generic associations). Thesauri can be encoded using the SKOS language or more expressive languages, such as RDFS or OWL2 (<http://www.w3.org/TR/skos-reference>). The latter two are commonly used for sharing and connecting data as knowledge graphs, which support some basic semantic reasoning.

Terminological clarification and disambiguation is about precisely defining terms and, in the process, distinguishing and relating different *word senses* of terms (e.g., “well” for a bore hole to extract liquids/gases vs the space in a building containing a staircase) and nuances in its use (e.g., referring to a water or oil well; referring to the excavated hole only vs to the entire structure that includes container and liquid). A primary tool for disambiguation is natural language (“prose”) definitions. They are core to *dictionaries* but also incorporated into SKOS ontologies via the “skos:definition” attribute and into *WordNets* (Fellbaum 2006) that additionally relate words and word senses using semantic relationships such as synonymy and hyponymy. Ontologies specified in RDFS or OWL2 can also incorporate such definitions in comments (using “rdfs:comment”) but they are not formally interpreted.

Gazetteers, such as the USGS's Geographic Names Information System (GNIS) (<https://geonames.usgs.gov/>), are ontologies that clarify and disambiguate between geographic names using feature types (e.g., a town, county, or river),

meronomic relationships (e.g., the country or state where it is located), and precise locations (e.g., latitude and longitude).

Standardization is agreeing on a shared interpretation of terms for a specific domain to improve semantic interoperability. Because standards primarily guide the people developing such applications, nonformal representations consisting of conceptual models and natural language definitions of terms are most common, as exemplified by OGC's spatial data standards Simple Features (SFA) (<https://www.ogc.org/standards/sfa>) and GML (<https://www.ogc.org/standards/gml>) and their domain-specific standards such as GeoSciML (<https://www.ogc.org/standards/geosciml>) and WaterML (<https://www.ogc.org/standards/waterml>) for geologic and hydrologic data, respectively. Other standards additionally provide reference implementations or machine-interpretable versions, such as the OWL2 versions for Semantic Sensor Networks (SSN) (<https://www.w3.org/TR/vocab-ssn/>), PROV-O (<https://www.w3.org/TR/prov-o/>), and OWLTime (<https://www.w3.org/TR/owl-time/>). Such formalized standards are critical for increasing information integration and exchange across geoscience applications geosciences and, specifically, for constructing spatial data infrastructures (SDI) and knowledge graphs.

Reference ontologies (Menzel 2003) play important standardization roles. *Foundational* (or *upper*) *reference ontologies* (Guizzardi 2010) provide anchor concepts refinement by other ontologies, while *domain reference ontologies* (Hahmann and Stephen 2018) provide domain-specific reference concepts. Both kinds are discussed further in the categorization by scope.

Semantic reasoning is about inferring implicit knowledge and requires expressive formal ontologies – also called **knowledge representation ontologies** (Jakus et al. 2013) – specified using logic-based languages such as OWL2 (or other Description Logics), SWRL (<https://www.w3.org/Submission/SWRL/>) or first-order logic (or Common Logic) (https://standards.iso.org/ittf/PubliclyAvailableStandards/c066249_ISO_IEC_24707_2018.zip). By relating terms flexibly via logical axioms, these languages enable complex automated reasoning about the interaction of classes and relations, such as about the domain or range of objects participating in a relation, or the existence of specific relations for certain types of objects. Querying and reasoning with such ontologies is facilitated by SPARQL (<https://www.w3.org/TR/rdf-sparql-query/>) (for RDFS, OWL2) and GeoSPARQL (<https://www.ogc.org/standards/geosparql>), Description Logic reasoners, or first-order theorem provers and model finders.

Categorizing Ontologies by Scope

Ontologies can also be categorized by scope, that is, how broadly applicable they are, ranging from top-level ontologies, generic ontologies, domain and domain reference ontologies, to highly specialized application ontologies. With narrowing scope the ontologies' depth can increase.

Top-level (or **upper** or **foundational**) **ontologies**, such as BFO or DOLCE and surveyed by Mascardi et al. (2007), define high-level categories of objects according to a certain philosophical perspective. They are primarily used for reference purposes (Menzel 2003) with challenges and limitations discussed by Grüninger et al. (2014). Common distinctions are between *endurants* (also called *continuants*: entities that are entirely present at a given time), *perdurants* (also called *occurents*: entities that are by nature defined over time, such as events or processes) and *qualities* (e.g. a temperature, color, or spatial location). Endurants are sub-categorized into physically present ones, including material (e.g. towns or water bodies) and immaterial ones (a hole), and non-physical endurants such as social or mental objects. DOLCE further distinguishes abstract objects, such as a “space region”, while BFO emphasizes the difference between independent and dependent objects (e.g. boundaries and holes depend on a host object). Perdurants are commonly categorized into events, processes, and states. Foundational relations include *parthood* (temporal or spatial), *constitution* and *dependence* as well as relations linking perdurants to endurants, such as DOLCE's *participation* relation. Ongoing work streamlines the top-level ontologies, including a new modular one (TUpper: Grüninger et al. 2014) within a single ISO standard (Draft standard ISO/IEC: 21838 with Parts for BFO and proposed parts for DOLCE and TUpper.).

Generic ontologies (Grüninger et al. 2014) and **mid-level ontologies** encompass concepts that are used across multiple domains, such as pertaining to space, time, processes, events, observations, or the provenance of information. These generic concepts play critical roles in the mathematical geosciences and the ontologies are intended to be either reused by or used in conjunction with domain and application ontologies. While foundational ontologies also contain generic concepts, purpose-built generic ontologies flesh them out. For example, DOLCE and BFO know “space regions” whereas spatial ontologies like for the FOL formalizations of Simple Features and CODIB define entire hierarchies of different kinds of spatial regions based on dimension, curvature, and configuration (FOL and OWL2 axiomatizations available from http://colore.oor.net/simple_features/ and http://colore.oor.net/multidim_space_codib/).

Domain ontologies cover a specific domain of interest, but vary in domain breadth. For example, GeoSciML covers all kinds of geological formations, while the WaterML parts Hy_Features and GWML2 more narrowly focus on surface and subsurface hydrology, respectively. These are typical geoscience domain ontologies in that they cover a breadth of concepts and attributes for describing data in their respective domains. In comparison, a *domain reference ontology* (variably also called a *reference domain ontology* or *core ontology*), such as the hydro foundational ontology (HyFO; Hahmann and Stephen 2018) or the GeoSciMLBasic module

of GeoSciML, strictly focuses on the high-level concepts needed to integrate ontologies within their domains.

Application ontologies are tailored to specific software systems, for example to describe data models or to enable data retrieval. Their specific nature and ad-hoc development often prevents reuse elsewhere. Examples are ontologies specifically developed to identify rock formations for natural resource extraction, or the data model underlying the National Hydrographic Dataset (<https://www.usgs.gov/core-science-systems/ngp/national-hydrography/national-hydrography-dataset>) that encodes the US stream network and flows.

Categorizing Ontologies by Representation Format

A wide spectrum of representations that differ in (1) formality and (2) expressivity are available (Table 2) for the varied uses

of ontologies (as summarized by Table 3). With respect to formality, we distinguish formal formats from non-formal ones. Expressivity is about how granular and detailed the semantics of terms can be specified.

Formality: The least formal, mostly conceptual, ontologies use graphical notations, such as Entity-Relationship Models or UML class diagrams (examples in Fig. 1), that lack machine-interpretability but are appropriate for communication between people. Semi-formal ontologies include thesauri (e.g., WordNets or SKOS ontologies) that utilizes multiple explicit – though vaguely defined – semantic relationships. On the other end of the spectrum are **formal ontologies** specified using machine-interpretable languages such as RDFS, OWL2 (and other Description Logics), rule languages (SWRL), first- and higher-order logics (examples in Table 1).

Ontology, Table 2 Common types of ontologies by representation format in increasing order of expressivity

Nonformal ontologies	Formal ontologies
Topic Map, Concept Map: <i>Graphical representation of concepts with labeled (Concept Map) or unlabeled (Topic Map) relationships between the concepts</i>	Resource Description Framework Schema (RDFS): <i>XML-based notation for declaring classes, properties, and individuals and relating them via hyponymy relations (subclassOf, subPropertyOf) and domain and range restrictions of properties in terms of classes. Can alternatively be serialized as triples of the form “subject predicate object” in the widely used Turtle or N-Triples notations or in JSON-LD</i>
Entity-Relationship Model: <i>Graphical representation showing relationships between named classes of objects and named properties/relations</i>	
Controlled Vocabulary, Term List, Glossary: <i>A set or list of terms for a domain/application of interest, called a glossary if in alphabetic order</i>	Web Ontology Language (OWL 2): <i>An extension of RDFS that allows more complex class descriptions and constructs for restricting the interaction of properties and classes. For example, complex classes can be constructed using logical connectives (intersection, union, complement), using existential and universal quantification and cardinality restrictions</i>
Semi-formal ontologies	
Dictionary: <i>A set of terms (typically in alphabetic order) with concise natural language definitions</i>	
Taxonomy: <i>A set of classes related hierarchically via “is-a” (hyponymy/subclass) relationships</i>	Semantic Web Rule Language (SWRL): <i>Extends OWL with rules, that is, axioms of the form “antecedent (body) - > consequent (head)” where body and head are conjunctions of statements</i>
Thesaurus (including SKOS and WordNet): <i>A set of classes related via taxonomic and other semantic relationships such as synonymy or meronymy (part-of)</i>	First-order logic (FOL; including Common Logic): <i>Logic language that allows free-from axioms using standard logical connectives (not, and, or, if, iff) over a vocabulary of classes and relations of arbitrary arity. Common Logic provides additional constructs for, e.g., specifying axiom schemata and or to scope axioms to specific classes</i>
UML Class Diagram: <i>Graphical representation that enhances ER models by taxonomic and meronomic relationships.</i>	

Ontology, Table 3

Common representation formats for ontologies and their most common uses

Representation format	Common uses (by purpose)				
	Modeling	KOS	Term. C & D	Standards	Reasoning
Topic Map, Concept Map	X				
Entity-Relationship Model	X				
Controlled Vocabulary, Glossary		X		X	
Dictionary		X	X	X	
Taxonomy	X	X	X	X	
UML Class Diagram	X	X		X	
WordNet (Thesauri)			X		
SKOS (Thesauri)		X	X		
RDF-S		X	X	X	X
OWL2				X	X
SWRL					X
FOL				X	X

Expressivity: Non-formal ontologies range in expressivity from providing a single, unnamed generic semantic relationship as in topic maps to thesauri that incorporate multiple semantic relationships such as WordNet’s synonymy and synonymy and SKOS’ “closeMatch” and “broaderMatch”.

Formal ontologies exhibit more pronounced differences in expressivity, which gradually increases from RDFS to OWL2 and further to SWRL and first-order logic (FOL, Common Logic) and higher-order logics. Because they use a formal logic as representation language, DL and FOL ontologies are called **axiomatic ontologies**, whereas non-axiomatic ones are sometimes called “lightweight ontologies.” The term “axiomatic” emphasizes that they are not reliant upon predefined semantic relations but allow arbitrarily complex logical sentences to be used as axioms to constrain the semantics of terms. This vastly increases expressivity and the kind of queries that can be posed.

Summary

Ontologies are used in a multitude of ways by mathematical geosciences and related scientific communities (see also the survey on geospatial semantics by Kokla and Guilbert 2020): They help conceptualize domains, standardize terminology, enable information organization and retrieval, and support complex semantic reasoning. Ontologies also differ widely in scope and representation formats. Among the available representation formats, formal ontologies specified in languages such as RDFS, OWL2, and more expressive languages experience increased uptake by the community as they afford the greatest semantic clarity and support the overall trend toward semantically enabled, knowledge-intensive science.

Definition

The summary definition of *Open Data* is “data that can be freely used, modified, and shared by anyone for any purpose” (OKF 2015).

The acceptance of what qualifies as *open* is under constant revision. The first definition in its modern use was created by the Open Knowledge Foundation in 2005 and its most recent iteration (version 2.1) was established in 2015. Changes to this definition were made using community feedback in order to ensure improved reusability, licensing, and attribution of the data.

Prerequisites of Open Data

The Open Definition (OKF 2015) describes in rigorous detail what elements are required, recommended, or optional to meet the criteria for Open Data. This poses conditions for the data itself (open works) and the license that will be associated with the data.

There are four criteria that the data must satisfy in order to classify as open: (1) it must have an open license, or be freely available in the public domain, (2) it must be accessible at most at a one-time reproduction cost and should be downloadable from the internet, (3) it needs to be compiled in a way

that makes it machine readable, and (4) the format in which the data is shared should be nonproprietary.

The license associated with Open Data must comply with the conditions of open licenses as outlined in Fig. 1. The differences between open licenses are important to understand, as they impose specific rights and responsibilities, both for data creators, as well as users.

Through a general licensing process, Open Data can be freely usable without any monetary compensation to its creator. It can be redistributed or sold, added to collections, and partial or derivative data must be distributed under the same license. Moreover, there must be no discrimination against any person or group, and all uses of the data are acceptable. The aforementioned conditions can only be changed under the following circumstances, which may be imposed by the license agreement:

- (i) Sharing the data requires that the creators will be cited (attribution).
- (ii) If any modifications are made to the data they will be clearly stated, or the name of the dataset will be changed or versioned (integrity).
- (iii) Redistributing the work will be done with the same license type (share-alike).
- (iv) Copyright and license information must be preserved (notice).
- (v) Distribution will be done in a predefined format (source).
- (vi) No technical restrictions will be imposed on distribution.
- (vii) Additional permissions and allowed rights can be granted to the public in cases such as patents (nonaggression).

Principles Surrounding Open Data

The Open Data ecosystem incorporates multiple participants throughout the data life cycle at many levels, such as governments, funding agencies, researchers, publishers, and end users. Some guiding principles have emerged, which aim to govern the complex rights and responsibilities of all stakeholders.

The International Open Data Charter (2015) put forth six principles to inform the use of Open Data with an emphasis on how government data should be shared in order to create more transparency and international collaboration. These principles stated that government data should be “*Open By Default, Timely and Comprehensive, Accessible and Usable, Comparable and Interoperable, For Improved Governance & Citizen Engagement, and For Inclusive Development and Innovation.*”

The need for regulating how data is shared was also identified as a priority within the scientific community, which led to the emergence of the FAIR Principles (*Findable, Accessible, Interoperable, Reusable*; Wilkinson et al. 2016). The FAIR principles provided a general framework for how Open Data should be shared and the importance of machine readability. They also recognize the need for data repositories to capture rich **metadata** – information that would accompany the data in order to make it more reusable. To further define the responsibilities of data repositories, a successor to the FAIR Principles was created: the TRUST Principles (*Transparency, Responsibility, User focus, Sustainability, and Technology*; Lin et al. 2020). Another complement to the FAIR principles is represented by the CARE Principles (*Collective Benefit, Authority to control, Responsibility, Ethics*; RDA 2019), a set of recommendations which aim to recognize and protect the value of Indigenous data.

Open Data, Fig. 1 Open License Conditions based on The Open Definition v 2.1 (OKF 2015)

State of Open Data

Since 2016, reports on the State of Open Data (Hyndman 2018) have been generated based on surveys of the scientific community. Researchers have been asked to share their views regarding their perception of Open Data.

The emerging trends show that more researchers are sharing their data, but fewer of them are reusing openly available data. There has been a declined interest among those that have not yet reused Open Data to start doing so. Of those researchers that have shared their data openly, almost half did not know under what license their data was shared. There is an increasing desire for more guidance and regulations to be put in place. The majority of researchers that were surveyed indicated that a national mandate for making primary research openly available is necessary (Fig. 2).

There are many organizations and collaborative projects that are working toward establishing more robust standards and best practices for data sharing and attribution. Initiatives such as Data Together (GO FAIR 2020) combine expertise from international organizations to ensure that the Open Data research ecosystem is governed, implemented, and maintained in a sustainable way.

Linked Open Data

The concept of Linked Data was introduced by Tim Berners-Lee (2006) in the W3C community as a way to regulate data sharing through the Semantic Web: Linked Data should have

a Uniform Resource Identifier (URI) that uses HTTP protocol, links to other URIs, and it should use standardized querying languages such as SPARQL or the Resource Description Framework (RDF). If the Linked Data uses open sources, it becomes Linked Open Data (LOD).

LOD adds value and increases the trustworthiness of data making it very powerful. When combined with open interfaces (APIs) to facilitate automation, LOD allows for better integration, discoverability, and access to complex data.

Open Data in Geosciences

From a data perspective, Earth and Space Sciences are made up of disparate long tail subdomains – data is primarily shared in discreet amounts, with not enough attention being given to interoperability or reusability.

Both technical infrastructure and governance initiatives regarding data stewardship in the geosciences have been gaining more momentum over the last decade. A variety of Open Data providers, tools, and platforms has emerged and is being maintained by large public funding agencies (see Ma 2018 for review). Requirements for newly published data to be open and interoperable by default, as well as legacy data rescue efforts are leading to large amounts of Open Data.

Technological advancements such as cloud computing and high-performance computing (HPC) are enabling large scale reuse of Open Data. Software deployments such as the Pangeo Environment (Odaka et al. 2020) offer solutions for

Open Data, Fig. 2 Trends emerging from surveys of researcher attitudes toward Open Data between 2016 and 2020. (Data from Hyndman 2018)

big data geoscience research that rely on, and concurrently generate, Open Data. Public access to these types of technologies is promoting open science on scales never seen before, facilitating cross-domain research and international collaboration.

Summary or Conclusions

Open Data is the most important building block of open science and scholarship. Big data studies and cloud computing rely on having a steady supply of high quality, metadata-rich, freely accessible, and machine-readable data. This has been historically a burden on data creators, but we are witnessing a perception shift, where it is understood that this is a shared responsibility. Better practices regarding data dissemination are being implemented on every level, from education to publication. The integrity of our data is the key to our shared knowledge – there is an inherent duty to preserve it, and ensure that it is open to all.

Definitions

Geoscience: The study of earth is called as geoscience. It investigates the processes that shape the earth's surface, the natural resources that we utilize, and how water and ecosystems are interrelated. Geoscience encompasses so much more than rocks, debris, and volcanoes.

Optimization: A process that takes the action of making the best or most effective use of a situation or resource.

Optimization problem: Maximizing or minimizing a specific function in relation to a set, which frequently represents a set of possibilities in a given circumstance. The function makes it possible to compare several possibilities that could be the “best.”

Background

The world is confronted with enormous problems that have ramifications for global socioeconomic performance and quality of life. To prevent and overcome the chaos created by global change, the new solutions are of utmost needed. In order to achieve this aim, better solutions need to be

developed to optimize the management of natural resources, identify new ways to exploit geophysical processes and characteristics, and apply geoscience knowledge to explore new and optimized methods of utilizing terrestrial resources. One of the most challenging tasks in modelling of geophysical and geological processes is to address large data and achieve specified objectives. Therefore, it can be considered as an optimization problem, which allows the use of several new effective optimization techniques. This article provides insight into how optimization can be utilized in geoscience study and how optimization and geoscience should coexist in the future.

What is Optimization?

Optimization is a search process which makes an object or system as useful or effective as feasible. It refers to determine the optimal solutions to meet a given objective subject to certain conditions. The purpose of optimization is to find the best possible solutions while taking into account the problem constraints. Optimization approaches are used to address the complicated scientific and engineering problems. The use of optimization techniques is vital due to time consumption and complexity of existing methods. Various complex engineering problems that demand computational precision in short time cannot be solved using traditional approaches. In this scenario, the optimization techniques are most effective approaches to find the best possible solution of such problems.

Initially, the heuristic optimization techniques explore randomly in the problem search space for the optimal solution with limited computation time and memory without requiring any complex derivatives (Osman and Laporte 1996). The term “heuristic” originated from the Greek word “heuriskein,” which means “to find.” In computing, the heuristic technique works on a rule-of-thumb for providing a solution to the problem despite of considering the repetitive application of the method. However, this method only searches for an estimated solution and does not require any mathematical convergence proof.

The most common and advanced heuristic optimization technique utilized in the context of addressing search and optimization issues is the metaheuristic optimization algorithm that was first proposed by Glover (1986). This method denotes a technique that employs one or more heuristics and hence possesses all the aforementioned features of heuristic method. As a result, a metaheuristic technique has many properties such as it tries to discover a near optimal solution rather than attempting to find the exact ideal solution, typically lacks a formal demonstration of convergence to the optimal solution, and lastly, it requires less time to compute than other exhaustive searches. These approaches are iterative in nature, and frequently utilize stochastic processes to alter

one or more original candidate solutions during the search process (usually generated by random sampling of the search space). Due to the inherent practicality of many real-world optimization issues, classical optimization algorithms may not always be relevant and may not perform well in tackling such problems in a pragmatic manner. Despite disregarding the importance of classical algorithms in the optimization field, many researchers and optimization practitioners realized that the metaheuristic methods are able to obtain a near-optimal solution in a computationally tractable manner. Therefore, the metaheuristic techniques have become the most popular optimization technique in recent years due to their capacity to handle a wide range of practical problems and produce an authentic and reasonable solution.

The most common inspirations for metaheuristic techniques are natural, physical, or biological principles that can be imitated at a fundamental level using a variety of operators. The balance between exploration and exploitation is a recurring subject in all metaheuristics. The term “exploration” relates to how successfully operators diversify solutions in the search space. This feature provides the metaheuristic with a global search behavior. Moreover, the ability of the operators to use the knowledge provided from earlier iterations to increase search is referred as exploitation. The metaheuristic gains a local search feature as a result of this intensification. Some metaheuristics are more explorative than exploitative, whereas others are the inverse. The fundamental approach of randomly selecting answers for a set number of iterations, for example, constitutes a totally exploratory search. Hill climbing, on the other hand, is an example of totally exploitative search in which the present answer is progressively modified until it improves. Metaheuristics allow the user to balance between diversification and intensification via operator settings. Based on these characteristics, metaheuristic optimization algorithms have various advantages as compared to the classical optimization algorithms:

- Metaheuristic algorithms can deal with the P class issues easily under significant complex inputs which may be a challenge for other conventional techniques.
- Metaheuristics are useful in solving difficult NP problems which cannot be solved by any known algorithm in an acceptable time period.
- Metaheuristics, unlike most traditional techniques, do not require gradient knowledge and may thus be utilized with non-analytic, black box, or simulation-based objective functions.
- Due to the inherent stochasticity and deterministic behaviors, many metaheuristic algorithms have the ability to recover from local optima.
- Metaheuristics can also handle uncertainties occurred in objectives in a better way as compared to the classical

optimization methods because of the ability to recover from local optima.

- Lastly, most metaheuristics can accommodate multiple objectives with relatively minor algorithmic modifications.

Classification of Metaheuristic Optimization Algorithms

The most popular method of categorizing metaheuristic methods is based on the number of original solutions modified in subsequent rounds. Single-solution metaheuristics begin with a single starting solution that is iteratively modified. It is important to note that while the modification process may involve more than one solution, only one solution is employed in each subsequent iteration. On the other hand, population-based metaheuristics employ more than one starting solution. Multiple solutions are modified in each iteration, and some of them make it to the next iteration. The operators are used to modify solutions, which frequently employ particular statistical features of the population.

Metaheuristic optimization algorithms can also be classified on the basis of the domain in which they operate. These algorithms are commonly referred as “bioinspired” or “nature-inspired” umbrella words. They can, however, be

further subdivided into four categories (Fig. 1): evolutionary algorithms, swarm intelligence algorithms, physical phenomena algorithms, and nature-inspired algorithms. The evolutionary algorithms simulate many elements of natural evolution, such as survival of the fittest, reproduction, and genetic mutation. Swarm intelligence and nature-based algorithms replicate the group behavior and/or interactions of live species (such as ants, bees, birds, fireflies, glowworms, fish, white blood cells, bacteria, and so on) (Huqqani et al. 2022) as well as nonliving objects (like water drops, river systems, masses under gravity). The remaining metaheuristics, classified as physics-based algorithms, imitate different physical processes such as metal annealing, musical aesthetics (harmony), and so on.

Practical Applications of Optimization Algorithms in Geoscience

The optimization algorithms have been widely used in various practical applications related to geoscience such as mineral and water exploration, geological and geo-structural mapping, natural hazards analysis, earthquake prediction and control, and many more. A few of the applications are discussed in the section.

Optimization in Geosciences, Fig. 1 Classification of metaheuristic optimization algorithms

Land Cover Feature Extraction

The term “land cover feature extraction” refers to the process of excerpting features from images of land in diverse locations. This is useful for a variety of different difficulties, such as detecting ground water, locating a path in mountainous terrain, and so on. For the aim of land cover feature extraction in the Alwar area of Rajasthan, methods such as fuzzy set, rough-fuzzy tie-up, membrane computing, and BBO were used. The pixels in the image are classified into five categories: rocky, water, urban barren, and flora. On the same Alwar dataset, hybrid versions of several methods have also been implemented. The algorithms included hybrid of ACO-BBO, hybrid of ACO-PSO-BBO, hybrid of FPAB-BBO, and hybrid of biogeography-based optimization and geoscience (BBO-GS) (Goel et al. 2013). As a result, BBO-GS has shown to be the top performer for the task among all the implemented algorithms.

Groundwater Mapping Analysis

One of the most important case studies of geoscience applications is the groundwater analysis. Water resources, including surface water and groundwater, are vital for life on our planet that are regenerated via evaporation, precipitation, and surface runoff. According to recent climate change estimations, the water cycle will become more spatially and temporally heterogeneous, resulting in water demand exceeding supply (*Intergovernmental panel on climate change* 2014). Groundwater is described as saturated water that fills the pore spaces between mineral grains, cavities, and fractured rocks in a rock mass. According to the World Economic Forum, scarcity of water will be a worldwide issue in the future. Consequently, about 20% of water utilized by humans is sourced from groundwater, and this proportion is expected to rise over the next few decades (Biswas et al. 2020). The extensive use of groundwater in agriculture, industry, and daily life causes several challenges to its management.

Generally, the hydrological testing, field surveys, and geophysical techniques are commonly used in groundwater research projects. These courses of action are time consuming, costly, and necessitate the use of skilled personnel. As a result, techniques for analyzing groundwater that may illustrate the hydrological connection with groundwater, such as the use of data-specific capacity, transmissivity, and yield, must be developed. Groundwater potential is often described as optimum zones for groundwater development or the likelihood of groundwater presence (Díaz-Alcaide and Martínez-Santos 2019). The likelihood of groundwater occurrence in a particular region is estimated using groundwater potential mapping which entails statistical analysis of many forms of field data. Remote sensing data acquiring techniques increase spatial coverage, thus improving the variety and availability

of data. GIS technology may be utilized to analyze vast regions at lower cost. Preliminary GIS studies utilizing machine learning and statistical techniques, among other things, might be beneficial for analyzing groundwater availability based on topographical and geographical parameters. As a result, prospective ground-water wells may be plotted to aid in groundwater detection.

With the rapid growing and complexity of data in GIS, a trustworthy model was necessary to assist in groundwater issue. Several models have been proposed to assess groundwater potential, including FR, WoE, and EBF models, as well as machine learning models such as ANN, RF, LR, and SVM. Some of these studies still have limitations in their predictions, which are impacted by the quality of the data collection and the internal structure of the model (Chen et al. 2019). Fadhillah built the groundwater potential mapping using a machine learning technique based on SVR with training data obtained from a hydraulic transmissivity dataset (Fadhillah et al. 2021). The learning process and the consistency of model outcomes can be influenced by SVR parameter settings. As a result, defining operational parameters becomes a problem in achieving the desired outcomes. To overcome this problem, he applied two metaheuristic optimization algorithms: GWO and PSO. GWO is an optimization method that has been frequently employed in GIS applications to optimize models. Due to its outstanding features above other swarm intelligence methods, it has been widely adapted for a broad variety of optimization problems (Faris et al. 2018). It has relatively few parameters, and no derivation information is necessary in the first search. Similarly, PSO is regarded as dependable in the computational process for model optimization since it provides a gentle computation and rapid convergence. It is believed that by employing the optimization technique, the groundwater model's performance would increase. By adjusting the SVR machine learning parameters, the metaheuristic optimization technique has the potential to improve model prediction accuracy.

Oil and Gas Reservoir Exploration

In resolving geophysical optimization issues, optimization algorithms have been utilized in two ways: either by performing the optimization or by optimizing parameters of other techniques (e.g., neural networks) used in various problems.

In a study on reservoir model optimization to match previous petroleum production data, a few optimization techniques are compared to PSO (Hajizadeh et al. 2011). In a case study involving two petroleum reservoirs, ACO, DE, PSO, and the neighborhood algorithm are combined in a Bayesian framework to assess the uncertainty of each algorithm's predictions. Ahmadi predicted reservoir permeability

using a soft sensor based on a feed-forward artificial neural network, which was subsequently improved using a hybrid GA and PSO approach (Ali Ahmadi et al. 2013). A multi-objective evolutionary method discovers optimum solutions and surpasses a standard weighted-sum technique.

In a research of oil and gas fields, Onwunalu and Durlofsky used PSO to find the best well type and location (Onwunalu and Durlofsky 2010). The comparisons with a GA across several runs of both algorithms reveal that PSO surpasses the GA on average, although the benefits of using PSO over GA may vary depending on the scenario. Well placement problems were also considered by Nwankwor using a hybrid PSO-DE method (Nwankwor et al. 2013). Hybridized metaheuristic optimization algorithms are potentially beneficial in reservoir engineering problem.

Summary

In summary, there are a lot of optimization problems in geosciences, and they can be solved using metaheuristic optimization or hybridized metaheuristic optimization algorithms. Besides, optimization algorithms also play a vital role in determine the best parameter for other machine learning techniques.

Ordinary Differential Equations

R. N. Singh¹ and Ajay Manglik²

¹Discipline of Earth Sciences, Indian Institute of Technology, Gandhinagar, Palaj, Gandhinagar, India

²CSIR-National Geophysical Research Institute, Hyderabad, India

Definition

Ordinary differential equation – a differential equation that contains unknown functions of one independent variable and their ordinary derivatives.

Introduction

An ordinary differential equation (referred as ODE in literature) is an equation that contains the unknown variable y and its ordinary derivatives with respect to time (or space) t , which in general form can be expressed as

$$F(t, y, y', y'' \dots, y^{(n)}) = 0, \quad (1)$$

where $y' = dy/dt$, $\dots$, $y^{(n)} = d^n y/dt^n$. Here, n represents the highest order of the derivative and hence the order of the ODE. For a unique solution of this equation, we need n conditions. When these can be prescribed at a value of t , it is called initial value problem, and when these are prescribed at two values of t , it is called two-point boundary value problem. This equation can be written as a system of first-order differential equation as $dy/dt = f(y, t)$, where y is a n -dimensional vector.

In initial value problem, the values of y are given at $t = t_0$, $y(t_0)$. Initial value problem is well posed as its solution exists,

is unique, and depends continually on the given data in case both functions f and df/dy are continuous (Coddington 1989). The literature on this subject is vast, but in this entry, we focus on some ODEs used in geosciences and show their applications in solving problems relevant to understanding earth's evolution and processes.

Geosciences deal with the structure, processes, and evolution of earth, the knowledge of which is constructed by using physical, chemical, and biological laws and interpreting observations made above, on, and within the earth. ODEs play a very important role in improving our understanding of the earth, especially when long-term behavior of some aspect of the earth is to be studied, e.g., temporal evolution of the earth, because other spatial variations can be averaged to reduce a generalized model, represented by a partial differential equation (PDE) (see ► “Partial Differential Equations”), to an ODE. These are so-called box models which pervade earth studies, say in biogeochemical cycles. ODEs also arise when PDEs involved in spatiotemporal studies of the earth are decomposed into a set of ordinary differential equations. Although one can have a generalized n th order ODE (Eq. 1), most of geosciences problems can be described by first- and second-order ODEs. Therefore, we discuss linear first- and second-order ODEs in the next section. We then cover nonlinear ODEs which are used in system's thinking. This is followed by discussion on various solution methods. Finally, we illustrate several examples of ODEs used in geosciences.

First- and Second-Order Linear ODEs

First-Order ODEs

We frequently encounter growth and decay problems. Such problems are solutions of the first-order ODEs. We get the following first-order inhomogeneous equation in general case, for instance, in Newton's cooling problem used in the study of cooling of earth and geological bodies:

$$\frac{dy}{dt} = f(t)y + g(t), \quad (2)$$

where, $f(t)$ and $g(t)$ are time-dependent coefficients in general form.

The solution of this equation is obtained by first multiplying both sides by $e^{-\int f(t')dt'}$ and then rearranging the equation as

$$\frac{d}{dt} \left(e^{-\int f(t')dt'} y \right) = e^{-\int f(t')dt'} g(t), \quad (3)$$

which has the general solution as

$$y(t) = C e^{\int f(t')dt'} + e^{\int f(t')dt'} \int e^{-\int f(t')dt'} g(t'') dt''. \quad (4)$$

The value of the constant of integration C depends on the choice of an initial condition, i.e., $y|_t = 0$.

Second-Order ODEs

Second-order ODEs are more prevalent in geosciences as most physical laws are described by second-order equations, e.g., oscillatory phenomena, equations for which are expressed as

$$\frac{d^2 y}{dt^2} + a \frac{dy}{dt} + by = f(t), y(0) = c, \frac{dy}{dt}(t=0) = d, \quad (5)$$

where the coefficients a and b are taken as constants and $f(t)$ is the source function.

The solution of inhomogeneous equation comprises of general solution given by the homogeneous part, also called complementary function, and particular solution of the equation. The solution for the homogeneous part of the equation can be written in terms of elementary functions. The solution is assumed as

$$y(t) = C e^{mt}, \quad (6)$$

where C and m are constants. Substituting this equation in Eq. (5), we get the following polynomial equation

$$m^2 + am + b = 0. \quad (7)$$

This has two roots m_1 and m_2 , which can be real or complex conjugate. Thus, the solution is written as

$$y(t) = C_1 e^{m_1 t} + C_2 e^{m_2 t}. \quad (8)$$

When both roots are the same ($m_1 = m_2$), the solution is given as

$$y(t) = (C_1 + C_2 t) e^{m_1 t}. \quad (9)$$

For complex roots such as $m_1 \pm m_2$, the solution is given by

$$y(t) = e^{m_1 t} (C_1 \cos m_2 t + C_2 \sin m_2 t). \quad (10)$$

The particular solution is obtained by using the method of trial and error in simple cases when the right-hand side is made of power, exponential or trigonometric functions. Some general forms of particular solution taken are C , $Ct + D$, $Ct^2 + Dt + E$, Ce^{pt} , $C \cos pt + D \sin pt$.

In general case, the method of variation of parameters is used to get a particular solution. The particular solution is assumed as linear combination of solutions of homogeneous equation

$$y_p = C_1(t)y_1 + C_2(t)y_2. \quad (11)$$

This is substituted in the defining equation and resulting equation for $C_1(t)$, and $C_2(t)$ is solved. The values of constants are determined by the initial conditions.

Nonlinear Equations

Three such equations under this category are the logistic equation, the predator-prey equations, and the Lorenz equation. In the first two cases, analytical solution can be written whereas in the last case no analytical solution has been found so far.

The logistic equation, used in all population studies, is written as

$$\frac{dy}{dt} = ry\left(1 - \frac{y}{K}\right), \quad y(0) = y_0. \quad (12)$$

Here, K is called carrying capacity, which is the maximum value of the population growing with maximum rate of growth as r , called Malthusian parameter. The solution of this equation is

$$y = \frac{K}{1 + \left(\frac{K}{y_0} - 1\right)e^{-rt}}. \quad (13)$$

The predator (y)–prey (x) equations, also known as the Volterra-Lotka equations, are written as, p , q , r , and s being constants,

$$\frac{dx}{dt} = px - qxy, \quad \frac{dy}{dt} = -ry + sxy. \quad (14)$$

No general analytical solution has been obtained for these equations except for special cases of coefficients. However, an implicit solution can be obtained by combining these equations in the phase plane as $dy/dx = (-ry + sxy)/(px - qxy)$, and the solution is

$$sx - r \log x = p \log y - qy + C; C - \text{a constant} \quad (15)$$

This is a closed curve in phase plane (x , y). C is determined by initial conditions for (x , y). In this way, the nature of solution can be obtained.

Lorenz equations, constituted of three ODEs, also occur frequently in the study of chaos in geosciences. These are, σ , ρ , and β being constants,

$$\frac{dx}{dt} = \sigma(y - x), \quad \frac{dy}{dt} = x(\rho - z) - y, \quad \frac{dz}{dt} = xy - \beta z. \quad (16)$$

No exact analytical solution to these equations has been found. However, the nature of solution can be deciphered

using qualitative methods initially developed by Poincare for studying the stability of the solar/planetary systems.

Solution Strategies

Two-Point Boundary Value Problem

These types of problems are posed as, with y -a vector

$$\frac{dy}{dt} = f(y, t), \quad a < t < b. \quad (17)$$

The boundary conditions at both ends are given either values of y or $\frac{dy}{dt}$, written as

$$B(y(a), y(b)) = 0. \quad (18)$$

The process of solving boundary value problem is to reduce them to initial value problem. In shooting method, we assume missing initial value and solve the problem as initial value problem, $y(a) = x$. The solution is substituted in the boundary condition as

$$B(x, y(b; x)) = 0. \quad (19)$$

This is a nonlinear function, and its root can be found. Simple shooting which is done from the boundary can be extended to multiple shooting by dividing the whole interval into subintervals and then shooting from one end of subinterval and using continuity of values at the nodes.

Eigenvalue problems are also boundary value problems. Here, the aim is to find values of coefficients in the differential equation such that both equation and boundary value are satisfied. The problem is posed, here, y – a vector

$$\frac{dy}{dt} = \lambda f(y), \quad a < t < b; y(a) = 0 = y(b). \quad (20)$$

Functions satisfying boundary conditions are substituted in the equation to get an algebraic equation for eigenvalue. The roots of the equation are eigenvalues, and corresponding orthogonal functions are eigen functions (see ► [“Eigenvalues and Eigenvectors”](#)). In a simple case

$$\frac{d^2y}{dt^2} = -\lambda y; y(0) = 0 = y(b). \quad (21)$$

We have the solution of this equation as

$$y(t) = A \sin \sqrt{\lambda} t + B \cos \sqrt{\lambda} t, \quad (22)$$

where $y(0) = 0$ shows that constant $B = 0$. Thus, nontrivial solutions are possible if $\sin \sqrt{\lambda} b = 0$. The solution of this

equation gives eigenvalues of the $\lambda_n = (n\pi/b)^2$; $n = 1, 2, \dots$, and the solution of boundary value problem is $y_n = A \sin n\pi t/b$. After normalization, the eigen functions are $y_n = \sqrt{2/b} \sin n\pi t/b$.

Green's Function Approach

The Green's function is the solution of a differential equation when the inhomogeneous term is given by Dirac delta function. Thus, for the Green's function $G(t, t_0)$ of second-order differential equation, we have the defining equation as

$$\frac{d^2 G(t, t_0)}{dt^2} + p(t) \frac{dG(t, t_0)}{dt} + q(t)G(t, t_0) = \delta(t - t_0), \quad (23)$$

with the boundary conditions as

$$G(0, t_0) = 0 \text{ and } G(d, t_0) = 0. \quad (24)$$

By integrating the defining equation around $t = t_0$, the following two conditions should be satisfied

$$G(t, t_0)|_{t_0+} - G(t, t_0)|_{t_0-} = 0, \quad (25a)$$

$$G'(t, t_0)|_{t_0+} - G'(t, t_0)|_{t_0-} = 1. \quad (25b)$$

Thus, the expression for the Green's function is obtained from two solutions of the homogeneous equation, y_1 , satisfying boundary condition at $t = 0$, and y_2 , satisfying boundary condition at $t = d$, as

$$G(t, t_0) = \begin{cases} \frac{y_1(t)y_2(t_0)}{W(t_0)} & 0 < t < t_0 \\ \frac{y_2(t)y_1(t_0)}{W(t_0)} & t_0 < t < d \end{cases} \quad (26)$$

This method helps to solve inhomogeneous ODEs.

Transform Methods

Initial value problem of ODEs can be converted to solving an algebraic equation after taking Laplace transformation (see ► “Laplace Transform”). After obtaining solution of this equation, inverse Laplace takes solution in transform domain to original domain. Laplace and inverse Laplace transform are defined as

$$Y(p) = L \{y(t)\} = \int_0^\infty e^{-pt} y(t) dt, \quad (27)$$

$$y(t) = L^{-1}Y(p) = \frac{1}{2\pi i} \int_{\sigma-i\epsilon}^{\sigma+i\epsilon} e^{pt} Y(p) dp; \operatorname{Re}(p) = \sigma. \quad (28)$$

Applying this to a simple first-order ODE

$$\frac{dy}{dt} = -ay, y(t=0) = y_0, \quad (29)$$

the result is

$$pY - y_0 = -aY. \quad (30)$$

Solving for Y and taking inverse Laplace transformation give

$$y(t) = y_0 e^{-at}. \quad (31)$$

This approach can be used for any order of ordinary differential equations.

Linear Systems

With the advent of computers, such equations are written in matrix form as

$$\frac{d}{dt} \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ b & a \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} + \begin{bmatrix} 0 \\ f(t) \end{bmatrix}. \quad (32)$$

This is further written as

$$\frac{dz}{dt} = Mz + g. \quad (33)$$

This is an example of linear dynamical system. The solution is written by mimicking first-order equation as

$$z = Ce^{Mt} + \int e^{M(t-t')} f(t') dt \quad (34)$$

There are large numbers of ways to calculate the exponential of a matrix. Best way is to use the method of singular value decomposition of a matrix. This matrix approach can be generalized to N number of equations. Constants are determined using the initial/boundary conditions (for finite intervals in t).

Numerical Solution

The ordinary differential equations, such as y -scale (vector)

$$\frac{dy}{dt} = f(y, t), y(t_0) = y_0, \quad (35)$$

are approximated by, e.g., the Euler method as

$$\frac{dy}{dt} \approx (y(t + \Delta t) - y(t)) / \Delta t, \quad (36a)$$

$$y(t + \Delta t) = y(t) + \Delta t f(y(t), t) + O(\Delta t^2), \quad (36b)$$

or more generally, with higher order schemes, say the Runge-Kutta, the fourth order, as

$$k_1 = \Delta t f(y_n, t_n), \quad (37a)$$

$$k_2 = \Delta t f\left(y_n + \frac{k_1}{2}, t_n + \Delta t/2\right), \quad (37b)$$

$$k_3 = \Delta t f\left(y_n + \frac{k_2}{2}, t_n + \Delta t/2\right), \quad (37c)$$

$$k_4 = \Delta t f(y_n + k_3, t_n + \Delta t), \quad (37d)$$

$$y(t_n + \Delta t) = y(t_n) + (k_1 + 2k_2 + 2k_3 + k_4)/6 + O(\Delta t^5). \quad (37e)$$

Now, powerful computer codes are available to solve system of ODEs, both nonstiff and stiff, such as `odeint()` method from `scipy.integrate` python module.

Special Functions

In simple cases, the solutions are made of elementary functions such as exponential, logarithmic, trigonometric, or hyperbolic equations. But when the coefficients of the second-order equations are a function of time, i.e.,

$$\frac{d^2 y}{dt^2} + p(t) \frac{dy}{dt} + q(t)y = 0, \quad (38)$$

it is no longer possible to write solution in terms of elementary equations. There are a large number of special functions worked out in various applications. The solutions are written in series form as

$$y = \sum_{n=0}^{\infty} a_n t^n. \quad (39)$$

This is substituted in the equation, and by equating the coefficients of t^n , the values of a_n 's are determined. If coefficients are singular, the expansion is taken around those points under some regularity conditions. Some frequently occurring special function equations are as follows (Arfken et al. 2015):

Bessel's Equation: $x^2 y'' + x y' + (x^2 - p^2)y = 0$

Legendre's Equation: $(1 - x^2)y'' - 2xy' + p(p + 1)y = 0$

Hermite Equation: $y'' - 2xy' + py = 0$

Gauss Hypergeometric Equation: $x(1 - x)y'' + [c - (a + b + 1)x]y' - aby = 0$

Laguerre's Equations: $xy'' + (1 - x)y' + py = 0$

Chebyshev's Equation: $(1 - x^2)y'' - xy' + p^2 y = 0$

Airy's Equation: $y'' \pm p^2 xy = 0$

In the above, p , a , b , and c are constants. All these function values are tabulated in the literature. These functions appear in describing wave and diffusion phenomena in the earth. As we need to compute the special functions, now it is preferable to use numerical solution of ordinary differential equations.

Qualitative Methods

Sometimes, it is not possible to find the solution of nonlinear problems. In such cases, it is still possible to find the solution in a qualitative form. This method was developed in the beginning of this century when Poincare' studied the problem of planetary system stability. Instead of determining the trajectory of planetary system, he devised methods to know whether such a system is stable or unstable. For instance, we are given

$$\frac{dy}{dt} = f(y). \quad (40)$$

We can find the equilibrium points of this problem by solving $f(y_e) = 0$. We can also find the stability of the equilibrium point y_e by finding the Jacobian $\partial f / \partial y$ at $y = y_e$. The nature of eigenvalues gives the nature of stability/instability. Such studies have been done in studying earth systems (Kaper and Engler 2013).

This can be demonstrated by a simple case

$$\frac{dy}{dt} = \mu - y^2, \quad (41)$$

which has equilibrium points at $y_e = \pm\sqrt{\mu}$. The stability of the system is deciphered from the sign of the following expression evaluated at equilibrium points

$$\frac{df}{dy} = -2y \text{ at } y = y_e. \quad (42)$$

Thus, $y_e = \sqrt{\mu}(-\sqrt{\mu})$ is stable (unstable). This is called pitchfork bifurcation.

Example of ODEs in Geoscience

Geochronology

Estimation of the age of rocks is an important study area in geosciences to reconstruct the geological processes in time and evolutionary history of the earth. The problem of decay of radiogenic elements $N(t)$ with time, t , can be expressed in terms of a first-order ODE

$$\frac{dN(t)}{dt} = -\lambda N(t), \quad (43)$$

where λ is the decay constant. For prescribed initial condition $N|_{t=0} = N_0$, the solution is obtained as

$$N(t) = N_0 \exp(-\lambda t). \quad (44)$$

Since our interest is in finding age, the above solution gives

$$t = -\frac{1}{\lambda} \ln\left(\frac{N}{N_0}\right). \quad (45)$$

Here, we need the values of two unknown parameters λ and N_0 to get the age. λ can be obtained in terms of half-life ($t_{1/2}$) of the radioactive element, defined as the time when its initial concentration N_0 is reduced to half. From this, we get $\lambda = \ln 2/t_{1/2}$. However, N_0 is not known. To circumvent this unknown, concentration of the stable decay product, called the daughter product, is used which is related to the parent element as

$$D = N_0 - N = N(e^{\lambda t} - 1). \quad (46)$$

Thus, time is given in terms of the ratio, D/N , as

$$t = \frac{1}{\lambda} \ln\left(\frac{D}{N} + 1\right). \quad (47)$$

Many times, there is a decay series, daughter product decaying to its own daughter products. For the case of the daughter product decaying to its subproduct with the decay constant λ_1 , we get

$$\frac{dD}{dt} = \lambda N - \lambda_1 D = \lambda N_0 e^{-\lambda t} - \lambda_1 D. \quad (48)$$

The solution for D is

$$D = \frac{\lambda}{\lambda_1 - \lambda} N_0 (e^{-\lambda t} - e^{-\lambda_1 t}). \quad (49)$$

In case $\lambda \ll \lambda_1$, this equation reduces to the condition called secular equilibrium.

$$\lambda_1 D \approx \lambda N. \quad (50)$$

Energy Balance at the Earth's Surface

Earth surface receives short wave radiation from the Sun and emits long wavelength radiation. This is modified by the surface albedo, atmospheric greenhouse gases, and planetary heat capacity. Using black body radiation law, the energy balance equation at the earth's surface is written as (Kaper and Engler 2013)

$$C \frac{dT}{dt} = Q(1 - \alpha) - \sigma T^4. \quad (51)$$

The surface temperature, time, heat capacity, incident solar radiation, albedo, and Stefan-Boltzmann constant are denoted respectively by T , t , C , Q , α , and σ . Albedo is also a function of temperature. Thus, this nonlinear equation needs to be solved by numerical method. However, for constant albedo and Budykov approximation for outgoing radiation as linear function of T (in $^\circ\text{C}$) as $(A + BT)$, this is reduced to linear ODE given by

$$C \frac{dT}{dt} = Q(1 - \alpha) - (A + BT). \quad (52)$$

Such equation has been used to find changes in the earth when solar luminosity changes due to solar processes.

Evolution of Mantle Temperature

Earth's mantle cools via loss of initial heat and thermal convection. The ordinary differential equation for mantle average temperature is obtained by equating the rate of mantle temperature change with difference of heat due to exponentially decaying radiogenic heat $h_0 e^{-\lambda t}$, and cooling at the earth surface (q) (Korenaga 2016)

$$C \rho D \frac{dT}{dt} = \rho D h_0 e^{-\lambda t} - q(T). \quad (53)$$

Here C , D , and ρ are heat capacity, thickness, and density of mantle, respectively. In general, $q(T)$ is a nonlinear function; however, this is linearized as

$$q = q_0 + \frac{dq}{dT} (T - T_o). \quad (54)$$

Thus, we get a linear differential equation for the evolution of mantle temperature which can be easily solved.

Overland Flow on a Hillslope

First-order ODEs also describe the overland flow in one horizontal direction (x) on a hillslope (see ► “Earth Surface Processes”), as given by (Anderson and Anderson 2010)

$$\frac{dQ_x}{dx} = R - I. \quad (55)$$

Here Q_x , R , and I are water flux, rainfall, and infiltration, respectively. Using the following relation between water flux, velocity, U , and thickness of overland flow, h ,

$$Q_x = Uh, U = \frac{1}{f} \sqrt{ghS}, \quad (56)$$

where g and S are gravity acceleration and hillslope, respectively; the expression for the thickness of the overland flow with distance from the hill top is expressed as

$$h(x) = \left(\frac{f(R - I)}{gS} \right)^{2/3} x^{2/3}. \quad (57)$$

Crustal Geotherm

The defining equation for the steady-state temperature distribution with depth in the continental crust is obtained by using corresponding special case of the heat diffusion equation given by (Turcotte and Schubert, 2010)

$$K \frac{d^2 T}{dz^2} = -A(z). \quad (58)$$

Here, temperature, depth, thermal conductivity, and radiogenic heat source concentration are denoted by T , K , z , and $A(z)$, respectively. The boundary conditions given at the earth surface ($z = 0$) and at the base of the crust ($z = l$) are

$$T|_{z=0} = T_0 \text{ and } K \frac{dT}{dz} \Big|_{z=l} = q_l, \quad (59)$$

where T_0 is the surface temperature and q_l is the heat flux at the base of the crust. The distribution of the radiogenic heat sources is given by

$$A(z) = A_0 \exp\left(-\frac{z}{d}\right), \quad (60)$$

where A_0 and d are the concentration of radiogenic sources at the surface and the characteristic depth. The solution of the problem is

$$T = T_0 + \frac{q_l}{K} z - \frac{A_0 d^2}{K} (1 - e^{-z/d}). \quad (61)$$

This expression has been used extensively to derive crustal geotherms.

Diffusion of Magnetic Field in Crust

The magnetic field due to external electric currents diffuses inside the earth's crust and the skin depth of diffusion is determined in terms of electrical conductivity of the rocks. This distribution is governed by the Maxwell's equations. For the horizontal magnetic field component $b\hat{x}$ diffusing with depth, denoted by z positive downward, and having time variation as $e^{i\omega t}$, a special case of Maxwell's equations is obtained as

$$\frac{d^2 b}{dz^2} = -i\omega\mu_0\sigma b. \quad (62)$$

Here, electrical conductivity and permeability are denoted, respectively, by σ and μ_0 , and ω is the angular frequency of the signal. The part of the solution which decreases with depth is given by

$$b = b_0 e^{-(1+i)z/z_0}; z_0 = \sqrt{\frac{2}{\omega\mu_0\sigma}}, \quad (63)$$

where b_0 is the amplitude of the magnetic field at the earth's surface and z_0 is called the skin depth that represents the length scale of the diffusion.

Channel Flow in Orogens

In orogens, sometimes, deep rocks are exposed at the earth's surface, and to explain it channel flow is postulated. The equation for variation in horizontal velocity $u(z)$ with depth z in a viscous (μ – viscosity) channel of thickness d due to applied pressure gradient dp/dx is approximated from the Navier-Stokes equation as (Turcotte and Schubert 2014)

$$\mu \frac{d^2 u}{dz^2} = \frac{dp}{dx}. \quad (64)$$

With top velocity as u_0 and bottom velocity as 0, the solution of this equation is

$$u(z) = u_0 \left(1 - \frac{z}{d}\right) + \frac{1}{2\mu} \frac{dp}{dx} (z^2 - dz). \quad (65)$$

Such solutions have been used to explain exposure of deeper rock in the Himalayan orogen.

Hillslope Forms

Hillslopes have convex shapes, and their weathered products diffuse toward their base. In the presence of tectonic uplift (U), the steady state height of hillslope (denoted by $z(x)$, with diffusion coefficient as D) connected to a river at horizontal distance $x = L$ from its peak at $x = 0$, is expressed, along with boundary conditions, as (Anderson and Anderson 2010)

$$\frac{d}{dx} \left(D \frac{dz}{dx} \right) + U = 0, \quad \frac{dz}{dx}(x=0) = 0, \quad z(L) = 0. \quad (66)$$

The solution of the above equation is

$$z(x) = \frac{U}{2D} (L^2 - x^2). \quad (67)$$

How much sediment is being put into the river can be determined by deriving the value of the flux at the river associated with uplift.

Groundwater Mound

Steady state water table ($h(x)$, x – horizontal axis) in an aquifer (conductivity denoted by k) bounded by rivers on both sides ($h(x=0) = h_1$, $h(x=b) = h_2$) under recharge I is governed by second-order differential equation (see ► “Flow in Porous Media”) as (Anderson 2008)

$$\frac{d}{dx} \left(kh \frac{dh}{dx} \right) + I = 0. \quad (68)$$

The solution is easily written for constant recharge as

$$h = \left(h_0^2 + \frac{I}{k} (bx - x^2) + \frac{x}{b} (h_1^2 - h_0^2) \right)^{1/2}. \quad (69)$$

The expression can be used to calculate the amount of water exchange taking place between river and aquifer due to changes in recharge and river levels.

Carbon Cycle

The most important part of carbon cycle at shorter timescale is about how much carbon is being put into the ocean. This problem can be understood by making box model of the coupled ocean and atmosphere and using conservation of mass to find out stocks and fluxes from both boxes. In a simplest model, we have f for anthropogenic input to atmosphere, with fluxes from atmosphere (ocean) to ocean (atmosphere) $aC_A(bC_O)$

$$\frac{dC_A}{dt} = -aC_A + bC_O + f, \quad \frac{dC_O}{dt} = aC_A - bC_O. \quad (70)$$

In steady state, we have $C_A/C_O = b/a$. This equation in matrix form can be written as

$$\frac{d}{dt} \begin{bmatrix} C_A \\ C_O \end{bmatrix} = \begin{bmatrix} -a & b \\ a & -b \end{bmatrix} \begin{bmatrix} C_A \\ C_O \end{bmatrix} + \begin{bmatrix} f(t) \\ 0 \end{bmatrix}. \quad (71)$$

This matrix equation can be solved by using linear system method.

Geochemical Reactions

Most common reactions, such as dissolution, hydrolysis, hydration, and oxidation, occur near the earth's surface due to its interaction with the atmosphere. On the one hand, these provide chemical elements for life processes, and on the other, these also lead to environmental hazard. In a simple case, dissolution of carbon dioxide in water is written as

Such reactions can be described by a system of ordinary differential equations which would describe the changes in the concentration of various elements. We can write reaction equation for dissolution of carbon dioxide in water as

$$\begin{aligned} dx/dt &= -k_1x + k_{-1}y, & dy/dt \\ &= k_1x - k_{-1}y - k_2y + k_{-2}p, \end{aligned} \quad (74a)$$

$$dz/dt = -k_2y + k_{-2}p, \quad dp/dt = k_2y - k_{-2}p, \quad (74b)$$

where x , y , z , and p are concentration of $CO_2(g)$, $CO_2(aq)$, H_2O , and H_2CO_3 , respectively. Reaction constants for forward and backward reactions are denoted by k 's. These equations can be written in matrix form and solved by using matrix methods.

Geophysical Systems

Geophysical problems are represented by a set of partial differential equations. These problems are reduced to a set of ODEs after discretizing the spatial domain. Method of lines is a well-developed tool to take this approach. We consider a simple advection-diffusion PDE which occurs quite frequently in geoscience

$$\frac{\partial u}{\partial t} = a \frac{\partial u}{\partial x} + b \frac{\partial^2 u}{\partial x^2}. \quad (75)$$

The spatial derivatives are discretized for the domain ($1 < i < M$), which gives a set of ODEs as

$$\frac{du_i}{dt} = a \frac{u_{i+1} - u_i}{\Delta x} + b \frac{u_{i+1} - 2u_i + u_{i-1}}{(\Delta x)^2}; \quad 1 < i < M. \quad (76)$$

With requisite boundary and initial conditions, a solution can be obtained analytically or numerically. Similar approach is used to discretize space part of second-order diffusion and wave equations.

Summary

Ordinary differential equations (ODEs) pervade geosciences. When studying long-term behavior of earth, box models are used which are described by a set of ODEs. ODEs also occur when using system's thinking about earth. Also, when focus is on steady state and one space-dimensional problem, again ODEs are used. Further, numerical solutions of PDEs often are obtained by decomposing them into a set of coupled ODEs. Both initial and boundary value problems for ODEs have been developed along with eigenvalue/eigenvectors and

Green's function method. For variable coefficients, some solutions are written in terms of special functions, or recourse to numerical methods is taken using powerful computer programs like highly popular Python's `odeint()` method. This entry has described the ODEs as applicable to the earth problems.

Ordinary Least Squares

Christopher Kotsakis
Department of Geodesy and Surveying, School of Rural and Surveying Engineering, Aristotle University of Thessaloniki, Thessaloniki, Greece

Definition

Ordinary least squares. A mathematical framework for analyzing erroneous observations in order to extract information about physical systems based on simple modeling hypotheses.

Introduction

An important aspect of the geosciences is to make inferences about physical systems from imperfect data. For this purpose, it is often required to work with mathematical models linking a set of unknown parameters with other observable quantities through known equations. Least squares theory originated from the aforesaid necessity and provides a standard framework to obtain information about the physical world on the basis of inferences drawn from modeled observations in the presence of additive errors.

Initially motivated by estimation problems in astronomy and geodesy (Nievergelt 2000), least squares theory was developed independently by Gauss and Legendre around 1795–1820, about 40 years after the advent of robust L_1 estimation. Its historical tracing has been studied by several scientists (e.g., Seal 1967; Plackett 1972; Sheynin 1979; Stigler 1991), and it constitutes one of the most interesting disputes in the history of science. The remarkable monograph by Gauss (1823) already contains almost the complete modern theory of least squares including elements of the theory of probability distributions, the definition and properties of the Gaussian distribution, and a discussion of the Gauss-Markov theorem on the statistical properties of the least squares estimator. In this entry, we give a brief overview of *ordinary least squares (OLS)* which is the simplest manifestation of least squares theory for analyzing noisy data with deterministic parametric models.

General Setting of the Problem

Consider a known vector $\mathbf{l} = [l_1, l_2, \dots, l_n]^T$ of n observations. From physical, mathematical or empirical considerations, it is expected that these observations can be explained by a smaller set of m parameters $\mathbf{x} = [x_1, x_2, \dots, x_m]^T$ through a known predictive model

$$\mathbf{f} : \begin{cases} \mathbb{R}^m \rightarrow \mathbb{R}^n & (n > m) \\ \mathbf{x} \mapsto \mathbf{f}(\mathbf{x}) \end{cases} \quad (1)$$

which is represented by a nonlinear over-determined system of n equations with m unknowns

$$\mathbf{l} = \mathbf{f}(\mathbf{x}) \quad (2)$$

The fundamental problem to be discussed herein is the inference of the model parameters from the information contained in the observations through the inversion of the above system (Menke 2015). In most applications of physical sciences and engineering, such a system does not have an exact unique solution, that is, no parameter vector $\mathbf{x} \in \mathbb{R}^m$ exists that can reproduce the given data $\mathbf{l} \in \mathbb{R}^n$. This setback

originates from the unavoidable presence of errors in the redundant observations (and perhaps from hidden deficiencies in the model choice itself). Hence, to a certain degree of simplification, the above problem may be viewed as a quest for a unique solution among the infinite ones that satisfy the under-determined system of observation equations

$$\mathbf{l} = \mathbf{f}(\mathbf{x}) + \mathbf{v} \quad (3)$$

where the residual vector $\mathbf{v}$ contains the unknown observation noise and other possible errors due to imperfect data modeling. In this context, *OLS is an optimal method for solving the above system in order to obtain a best estimate of the model parameters based on algebraic or statistical principles.*

OLS: Algebraic Aspects

From an algebraic perspective, the rationale of OLS is to provide an estimator for the model parameters, denoted hereafter by $\hat{\mathbf{x}}^{OLS}$, that minimizes the Euclidean (squared) distance between the observations and their model-based prediction (Menke 1989; Rao and Toutenburg 1999)

$$\begin{aligned} \hat{\mathbf{x}}^{OLS} &= \arg \min_{\mathbf{x} \in \mathbb{R}^m} \left(\|\mathbf{l} - \mathbf{f}(\mathbf{x})\|^2 \right) \\ &= \arg \min_{\mathbf{x} \in \mathbb{R}^m} \left((\mathbf{l} - \mathbf{f}(\mathbf{x}))^T (\mathbf{l} - \mathbf{f}(\mathbf{x})) \right) \end{aligned} \quad (4)$$

The above solution does not rely on any stochastic or statistical considerations about the observation errors. It is merely a best-fitting solution in the sense of minimizing the residual vector in Eq. (3) or more precisely the sum of the squared values of its elements (hence the term “ordinary least squares”).

Model Linearization

To explicitly compute $\hat{\mathbf{x}}^{OLS}$ in practice, one first has to linearize the predictive model around known approximate values for the parameters $\mathbf{x}_o$ and then apply the least squares criterion to its linearized version in order to solve for the first-order corrections $\delta\mathbf{x} = \mathbf{x} - \mathbf{x}_o$. Of course, this step needs to be properly iterated (i.e., the solution of each step is used as initial approximation in the next step) until sufficient convergence is reached in the estimated parameters. As an alternative, instead of applying the OLS principle to the linearized model, one may directly solve the nonlinear optimization problem of Eq. (4) by using some well-known iterative technique (e.g., Gauss-Newton method, steepest descent gradient method). We prefer to follow the first approach here, since it is the one that is commonly used in least squares problems with nonlinear parametric models. For more details, see, e.g., Sen and Srivastava (1990, pp. 298–316).

In the following, it is assumed that the linearization of the predictive model $\mathbf{l} = \mathbf{f}(\mathbf{x})$ was applied beforehand. Moreover, for the sake of notation simplicity, we shall retain the same symbols in both sides of the linearized model which is expressed hereafter as $\mathbf{l} = \mathbf{A}\mathbf{x}$, instead of the lengthened form $\mathbf{l} - \mathbf{f}(\mathbf{x}_o) = \mathbf{A}(\mathbf{x} - \mathbf{x}_o)$. The Jacobian matrix $\mathbf{A} = \partial\mathbf{f}/\partial\mathbf{x}$, known as the *design matrix*, is computed with the help of approximate parameter values, and it needs to be updated during the iterative implementation of OLS estimation in nonlinear models.

Estimation of Model Parameters

Based on the previous linear(ized) framework, the objective function to be minimized in the optimal criterion of Eq. (4) takes the form

$$\begin{aligned} \|\mathbf{l} - \mathbf{f}(\mathbf{x})\|^2 &= (\mathbf{l} - \mathbf{A}\mathbf{x})^T (\mathbf{l} - \mathbf{A}\mathbf{x}) \\ &= \mathbf{l}^T \mathbf{l} - 2\mathbf{l}^T \mathbf{A}\mathbf{x} + \mathbf{x}^T \mathbf{A}^T \mathbf{A}\mathbf{x} \end{aligned} \quad (5)$$

A necessary condition to minimize the last expression is the nullification of its partial derivative

$$\frac{\partial \|\mathbf{l} - \mathbf{f}(\mathbf{x})\|^2}{\partial \mathbf{x}} = -2\mathbf{l}^T \mathbf{A} + 2\mathbf{x}^T \mathbf{A}^T \mathbf{A} = \mathbf{0} \quad (6)$$

which leads to the so-called normal equations

$$(\mathbf{A}^T \mathbf{A}) \mathbf{x} = \mathbf{A}^T \mathbf{l} \Leftrightarrow \mathbf{N} \mathbf{x} = \mathbf{b} \quad (7)$$

where $\mathbf{N} = \mathbf{A}^T \mathbf{A}$ is called the *normal matrix*. If the design matrix $\mathbf{A}$ has full rank, then the normal matrix is invertible and the normal equations admit a unique solution which is the OLS estimator of the model parameters (Koch 1999; Rao and Toutenburg 1999)

$$\hat{\mathbf{x}}^{OLS} = \mathbf{N}^{-1} \mathbf{b} = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \mathbf{l} \quad (8)$$

Model-Based Prediction

In practice, the user’s interest may be confined on $\hat{\mathbf{x}}^{OLS}$ or it may extend to its predictive ability for other quantities that depend on the model parameters – such quantities are called *response variables* in the terminology of regression analysis (Draper and Smith 1998; Sen and Srivastava 1990). In fact, the observations that were used to estimate the model parameters can be predicted anew as follows:

$$\hat{\mathbf{l}}^{OLS} = \mathbf{A} \hat{\mathbf{x}}^{OLS} = \mathbf{A} (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \mathbf{l} = \mathbf{H} \mathbf{l} \quad (9)$$

where $\mathbf{H} = \mathbf{A} (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T$ is an important matrix, called the *hat matrix*, which executes the orthogonal projection from the observation space $\mathbb{R}^n$ onto the column space of the design

matrix. The latter is denoted as $\text{Im}\{\mathbf{A}\}$, and it corresponds to a particular subspace of $\mathbb{R}^n$ spanning all possible predictions of the observables via the adopted model, that is, $\text{Im}\{\mathbf{A}\} = \{\mathbf{A}\mathbf{x}, \mathbf{x} \in \mathbb{R}^m\}$. The hat matrix is symmetric and idempotent while its trace is equal to the number of model parameters ($\text{tr} \mathbf{H} = m$). The predicted vector in Eq. (9) upgrades the original observations in the sense of reducing (not eliminating) their random errors to get new values that are compatible with the parametric model – this replacement of $\mathbf{l}$ by $\hat{\mathbf{l}}^{OLS}$ is generally termed *least squares adjustment* (Teunissen 2000).

Residuals

The OLS residuals reflect the difference between the original observations and their model-based predictions, and they are given by the equation

$$\begin{aligned} \hat{\mathbf{v}}^{OLS} &= \mathbf{l} - \mathbf{A} \hat{\mathbf{x}}^{OLS} = \mathbf{l} - \mathbf{A} (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \mathbf{l} \\ &= (\mathbf{I} - \mathbf{H}) \mathbf{l} \end{aligned} \quad (10)$$

where $\mathbf{I}$ is the $n \times n$ unit matrix and $\mathbf{I} - \mathbf{H}$ corresponds to the orthogonal projector from the observation space $\mathbb{R}^n$ onto the orthogonal complement of $\text{Im}\{\mathbf{A}\}$. This matrix is also symmetric and idempotent, while its trace is equal to the *degrees of freedom* of the estimation problem at hand ($\text{tr}(\mathbf{I} - \mathbf{H}) = n - m$). The OLS residuals give a useful metric for the effectiveness of the solution, but they cannot be exploited in more comprehensive quality analyses or statistical testing procedures without the aid of auxiliary hypotheses for the observation errors.

Geometrical Interpretation of OLS

The OLS method provides a best estimate of the model parameters by splitting the observations into two orthogonal components: a model-based predicted part and a residual part

which is attributed to measurement and/or modeling errors. This decomposition is algebraically expressed as

$$\mathbf{l} = (\mathbf{I} - \mathbf{H}) \mathbf{l} + \mathbf{H} \mathbf{l} = \hat{\mathbf{v}}^{OLS} + \hat{\mathbf{l}}^{OLS} \quad (11)$$

whereas the orthogonality condition $(\hat{\mathbf{l}}^{OLS})^T (\hat{\mathbf{v}}^{OLS}) = 0$ is easily verified from the properties of the hat matrix. The above splitting allows a simple geometrical interpretation of OLS which is depicted in Fig. 1.

OLS: Statistical Aspects

The algebraic formulation of the OLS method does not account for the nature of the residuals in the augmented system of observation equations. Its justification is based on the presumption that their values should be small (hence the reasoning of $\|\mathbf{v}\| \rightarrow \min$), a fact that implies the availability of a “good” dataset and the usage of a “correct” parametric model. The switch to a statistical formulation allows us to formalize those two assumptions while it offers the necessary framework to test their validity in practice and to assess the quality of the OLS solution.

Gauss-Markov Conditions

In the statistical context of OLS, the residuals in Eq. (3) are modeled as zero-mean random variables with common variance and zero covariances (Rao and Toutenburg 1999):

$$E\{\mathbf{v}\} = \mathbf{0}, \mathbf{D}\{\mathbf{v}\} = E\{\mathbf{v}\mathbf{v}^T\} = \sigma^2 \mathbf{I} \quad (12)$$

where $E\{\cdot\}$ is the expectation operator from probability theory, $\mathbf{D}\{\mathbf{v}\}$ is the covariance matrix (also called dispersion matrix) of the residual vector, and σ^2 is the common variance

Ordinary Least Squares, Fig. 1 The OLS solution is an orthogonal projection from the “observation space” $\mathbb{R}^n$ onto the “model space” $\text{Im}\{\mathbf{A}\}$. The columns of the design matrix form a (non-orthogonal) basis in the model space while the estimated parameters are the “coordinates” of

the model-predicted observables with respect to that basis. For easier visualization, it is assumed that the model contains only two parameters which correspond to columns $\mathbf{A}_1$ and $\mathbf{A}_2$ of the design matrix

of its elements. The above assumptions may also be expressed in the observation domain:

$$\begin{aligned} E\{I\} &= A x, \\ D\{I\} &= E\{(I - A x)(I - A x)^T\} = \sigma^2 I \end{aligned} \quad (13)$$

and they are known as *Gauss-Markov (G-M) conditions* which theoretically assure the statistical goodness of the OLS solution (Koch 1999). In simple words, these conditions dictate that the observations are free of any systematic errors, outliers, or blunders, and they are influenced only by (uncorrelated) random errors at the same accuracy level. Moreover, in the absence of such errors, the observations are expected to conform to a linear model which is specified through a full-rank design matrix of error-free elements (A) and a parameter vector with fixed but unknown values (x) that need to be estimated from a given ensemble of noisy observations.

Statistical Optimality of OLS Solution

If the G-M conditions hold true, then the OLS solution admits optimal properties that justify its use in real-life applications. Specifically, it becomes a linear unbiased estimator of the model parameters, that is

$$\begin{aligned} E\{\hat{x}^{OLS}\} &= E\{(A^T A)^{-1} A^T I\} \\ &= (A^T A)^{-1} A^T E\{I\} \\ &= (A^T A)^{-1} A^T A x \\ &= x \end{aligned} \quad (14)$$

whereas its covariance (dispersion) matrix is

$$\begin{aligned} D\{\hat{x}^{OLS}\} &= D\{(A^T A)^{-1} A^T I\} \\ &= (A^T A)^{-1} A^T D\{I\} (A^T A)^{-1} \\ &= \sigma^2 (A^T A)^{-1} A^T A (A^T A)^{-1} \\ &= \sigma^2 (A^T A)^{-1} \end{aligned} \quad (15)$$

and it has the smallest trace among any other linear unbiased estimator of x from the same data I (Rao and Toutenburg 1999; Koch 1999). The square roots of its diagonal elements reflect the (internal) accuracy of the estimated model parameters – also called standard errors – and they are used to describe the statistical goodness of the OLS solution at the parameter level. For example, the standard error of $\hat{x}_i$ denoted by $\sigma_{\hat{x}_i}$ is the square root of the i th diagonal element of $\sigma^2 (A^T A)^{-1}$, and it gives a measure of its likely offset from the true value of the respective parameter. For a more realistic assessment of the estimation accuracy, the standard errors are

usually amplified by a factor of 3 or 4 in order to increase their confidence level.

In a nutshell, the OLS solution minimizes the propagated observation errors to the estimated model parameters. The estimator $\hat{x}^{OLS}$ is the *best linear unbiased estimator* which offers optimal accuracy (minimum variance) in the presence of the G-M conditions. What is more, the statistical optimality extends to all model-based predictions that will use the OLS estimator to infer other quantities in a linear(-ized) context, that is, if $y = q^T x$, then its estimate $\hat{y}^{OLS} = q^T \hat{x}^{OLS}$ is unbiased and it has minimum variance among any other linear unbiased estimator of y from the same data. For more details, see Koch (1999) and the references given therein.

If the G-M conditions are invalid in practice, then the OLS solution does not necessarily become useless, yet its results lose their statistical optimality and may be affected by hidden biases. In such cases, the user needs to make appropriate changes to the data and/or the parametric model which would cause approximate compliance with the G-M conditions.

Other Statistical Properties

Based on Eqs. (9, 10), and after considering the properties of the hat matrix, one easily obtains the covariance matrix of the model-predicted observations

$$\begin{aligned} D\{\hat{l}^{OLS}\} &= D\{H I\} \\ &= H D\{I\} H^T \\ &= \sigma^2 H \end{aligned} \quad (16)$$

and also the covariance matrix of the OLS residuals

$$\begin{aligned} D\{\hat{v}^{OLS}\} &= D\{(I - H) I\} \\ &= (I - H) D\{I\} (I - H)^T \\ &= \sigma^2 (I - H) \end{aligned} \quad (17)$$

In contrast to $D\{I\}$, the covariance matrices $D\{\hat{v}^{OLS}\}$ and $D\{\hat{l}^{OLS}\}$ are always singular, and their diagonal elements have a key role in the statistical testing of observations regarding the presence of outliers. The last two equations imply the decomposition

$$D\{I\} = D\{\hat{v}^{OLS}\} + D\{\hat{l}^{OLS}\} \quad (18)$$

which is a manifestation of the orthogonality property of OLS in the stochastic domain. The model-predicted observations and the estimated residuals are actually uncorrelated with each other (Draper and Smith 1998)

$$E\left\{\hat{\mathbf{v}}^{OLS} \left(\hat{\mathbf{l}}^{OLS}\right)^T\right\} = \mathbf{0} \quad (19)$$

and, therefore, the sum of their covariance matrices will be equal to the covariance matrix of the observations. Note that the expected values of these quantities shall comply with the G-M conditions, that is, $E\left\{\hat{\mathbf{l}}^{OLS}\right\} = \mathbf{A} \mathbf{x}$ and $E\left\{\hat{\mathbf{v}}^{OLS}\right\} = \mathbf{0}$.

OLS and Maximum Likelihood Estimation

The OLS estimator does not require the probability distribution function of the observation errors. In fact, the only necessary stochastic elements that need to be specified through the G-M conditions are the first- and second-order moments of the observation vector $\mathbf{l}$. However, in case of normally distributed errors, the OLS estimator becomes equivalent with the maximum likelihood estimator which is inherently related to *Bayesian inference* under the hypothesis of uniform prior distribution for the model parameters (Rao and Toutenburg 1999).

Goodness of Fit

The evaluation of model fit is an important task that often needs to be performed in the context of OLS estimation. In general, a successful solution is characterized by small residuals which indicate a good fit of the observations to the parametric model (or vice versa). A number of relevant measures to quantify the goodness of fit of the solution are briefly described below. For a more detailed discussion, see the respective chapters in Draper and Smith (1998) and Sen and Srivastava (1990).

Residual Sum of Squares (RSS)

It corresponds to the (squared) Euclidean length of the OLS residual vector. Its value may be computed by three equivalent expressions as follows:

$$RSS = \left(\hat{\mathbf{v}}^{OLS}\right)^T \hat{\mathbf{v}}^{OLS} = \mathbf{l}^T (\mathbf{I} - \mathbf{H}) \mathbf{l} = \mathbf{l}^T \hat{\mathbf{v}}^{OLS} \quad (20)$$

The disadvantage of this quantity is its dependence on the units in which the observations are expressed, thus making it difficult to exploit the RSS for objective assessment of model fit performance. If the above value is divided by the degrees of freedom of the problem at hand, then we obtain an unbiased estimate of the variance of the (true) residuals in the respective model

$$s^2 = \frac{RSS}{n - m}, \quad E\{s^2\} = \sigma^2 \quad (21)$$

The above estimate (often called *residual mean square – RMS*) is useful if the data noise level is unknown, as it allows us to replace σ^2 with s^2 in order to infer the statistical accuracy of the results, e.g.

$$\mathbf{D}\left\{\hat{\mathbf{x}}^{OLS}\right\} = \sigma^2 (\mathbf{A}^T \mathbf{A})^{-1} \rightarrow \hat{\mathbf{D}}\left\{\hat{\mathbf{x}}^{OLS}\right\} = s^2 (\mathbf{A}^T \mathbf{A})^{-1} \quad (22)$$

The knowledge of noise level is not required in the numerical computation of the estimated parameters, but it is necessary for computing their associated covariance matrix. Obviously, for s^2 to be a meaningful estimate of the noise variance, it needs to be ensured that no “problematic” observations (in violation of the G-M conditions) were used in the OLS solution.

Coefficient of Multiple Determination

This is a unitless measure which is commonly used to evaluate the model fit in OLS problems (yet it requires caution when comparing different models with the same or several datasets). It is defined as

$$\begin{aligned} R^2 &= \frac{\sum_{i=1}^n \left(\hat{l}_i^{OLS} - \bar{l}\right)^2}{\sum_{i=1}^n \left(l_i - \bar{l}\right)^2} = \frac{\left(\hat{\mathbf{l}}^{OLS} - \bar{\mathbf{l}}\right)^T \left(\hat{\mathbf{l}}^{OLS} - \bar{\mathbf{l}}\right)}{\left(\mathbf{l} - \bar{\mathbf{l}}\right)^T \left(\mathbf{l} - \bar{\mathbf{l}}\right)} \\ &= 1 - \frac{RSS}{\left(\mathbf{l} - \bar{\mathbf{l}}\right)^T \left(\mathbf{l} - \bar{\mathbf{l}}\right)} \end{aligned} \quad (23)$$

where $\bar{l}$ denotes the mean value of the observations and $\bar{\mathbf{l}}$ is an auxiliary vector whose elements are all equal to $\bar{l}$. The value of R^2 ranges between 0 and 1, and it reflects the squared correlation coefficient between the observations and their model-predicted part. A perfect fit to the available data would give $R^2 = 1$ (since $RSS = 0$) which is a highly unlikely event in practice. In general, the closer its value gets to 1, the better is the model fit to the noisy observations.

The previous definition of R^2 relies on the assumption that the parametric model includes a constant term, which means that the design matrix $\mathbf{A}$ should contain a column full of ones (a constant term in a linear model is usually called the “intercept” in statistical literature). As a matter of fact, an alternative interpretation of R^2 is that it measures the usefulness of the extra terms other than the intercept in the parametric model (Draper and Smith 1998). Its value is not comparable between entirely different models, but it can be used to compare the fitting performance of nested models. As a result, parametric models which contain an intercept cannot be compared with those without intercept on the basis of R^2 .

Sometimes it is preferable to use an *adjusted* R^2 , denoted by R_a^2 , which is given by the formula (Sen and Srivastava 1990)

$$R_a^2 = 1 - \frac{\sum_{i=1}^n (\hat{l}_i^{OLS} - \bar{l})^2 / (n - m)}{\sum_{i=1}^n (l_i - \bar{l})^2 / (n - 1)} = 1 - (1 - R^2) \left(\frac{n - 1}{n - m} \right) \quad (24)$$

The above coefficient accounts for the sample size (i.e., number of available observations) since it is often felt that small sample sizes tend to inflate the value of R^2 . This revised metric can be used to compare different parametric models that may be fitted not only to a specific dataset but also to two, or more, different sets of observations. Note that R_a^2 may take negative values, and it practically serves as a gross indicator for the model fit in OLS problems.

Residual Analysis

The observations to be analyzed by least squares methods may be affected by outliers or blunders due to improper conditions in data collection or other external disturbances. Depending on the magnitude of such errors and the importance of the affected observables, the OLS solution may be seriously harmed even by a single bad observation. The analysis of residuals aims to identify bad observations which should be excluded from the estimation procedure as they violate the first of the G-M conditions in Eq. (13). One of the most important tips to remember here is the following: the OLS residuals do not correspond to the true observation errors but they are related to them through the orthogonal projection

$$\hat{\mathbf{v}}^{OLS} = (\mathbf{I} - \mathbf{H}) \mathbf{v} \quad (25)$$

Although the above equation does not have practical value, it shows that the OLS residuals always give a “blurred” snapshot of the true observation errors. In particular, a gross error in a single observation is partly “transferred” to the residuals of other observations, thus causing difficulties to isolate problematic observations solely on the basis of $\hat{\mathbf{v}}^{OLS}$.

Of special importance in residual analysis are the diagonal elements $\{H_{ii}\}$ of the hat matrix $\mathbf{H}$, which are linked with the variances of the model-predicted observations as follows

$$\text{var}\{\hat{l}_i^{OLS}\} = \sigma^2 H_{ii} \quad (26)$$

and they represent the so-called *leverages* of the respective observables (Belsley et al. 1980). Their values are always positive numbers between 0 and 1, and their importance should be mainly considered in a relative context: if an

observation has much higher leverage than the others, then it is poorly predicted by the model parameters, and its prediction is likely to absorb the largest part of a hidden outlier or blunder. The sum of the leverages is equal to $\text{tr } \mathbf{H} = m$ which means that their average value is $\bar{H}_{ii} = m/n$. Therefore, an alarm for very influential observations which may be outliers could be set if $\bar{H}_{ii} > 2m/n$ or maybe $\bar{H}_{ii} > 3m/n$ (Draper and Smith 1998). High-leverage observations usually originate from poor experimental design, and they pose a threat to the integrity of OLS solutions.

For the purpose of detecting bad observations that do not comply with the G-M conditions, more valuable than the ordinary residuals $\hat{\mathbf{v}}^{OLS}$ are the so-called standardized or (internally) studentized residuals given as

$$e_i = \frac{\hat{v}_i^{OLS}}{\left(\text{var}\{\hat{v}_i^{OLS}\}\right)^{1/2}} = \frac{\hat{v}_i^{OLS}}{s \sqrt{1 - H_{ii}}} \quad (27)$$

whose variance is always equal to 1. A modified version of the above residuals

$$e'_i = \frac{e_i \sqrt{n - m - 1}}{\sqrt{n - m - e_i^2}} \quad (28)$$

known as (*externally*) *studentized residuals* is mostly used in practice (Draper and Smith 1998). These residuals follow the t -distribution with $n - m - 1$ degrees of freedom under the normality assumption for the observation errors, and their values are used by most software packages as test statistics in single outlier detection.

Summary

Least squares theory carries a long history dating back to the late eighteenth century, and it offers a powerful framework for analyzing noisy data in a broad range of applications in physical sciences and engineering. The estimation problems that can be treated by the least squares methodology involve a variety of modeling setups with assorted complexity levels, which extend well beyond the simple OLS case that was covered in this entry. Most of these problems are of high relevance to various branches of mathematical geosciences, including the inversion of rank-deficient linear models with or without the presence of prior information, the least squares approximation of continuous signals from discrete observations, the handling of correlated data noise with regular or singular covariance matrix, the recursive estimation of time-varying parameters in dynamic systems (Kalman filtering), and the parameter estimation in the so-called errors-in-

variables models. On the other hand, the OLS methodology and its associated diagnostic tools remain an attractive option for handling parameter estimation and model-fitting problems with homogeneous datasets, having as major advantage the straightforward and easy-to-implement mathematical framework that was outlined in this entry.

Definition

Partial differential equation: A differential equation that contains unknown functions of two or more independent variables and their partial derivatives

Introduction

Geosciences use physical laws to derive information about the properties and processes in Earth based on observations of physical fields. Physical laws are those which govern mechanical, thermal, electromagnetic, and chemical behaviors of continuous media. These consist of conservation laws and constitutive relations. This leads to laws as a set of partial differential equations (PDEs) (Officer 1974; Kennett and Bunge 2008). PDEs in general form are written as a function of space, time, function, and its derivatives, i.e.,

$$f(x, y, z, t, \phi, \phi_x, \phi_y, \phi_z, \phi_{xx}, \phi_{yy}, \phi_{zz}) = 0, \text{ where } \phi_x \equiv \frac{\partial \phi}{\partial x}. \quad (1)$$

Most of the physicochemical processes in Earth are governed by second-order PDEs. Three classic examples of linear homogeneous PDEs, elliptic, parabolic, and hyperbolic types, respectively, are (Morse and Feshbach 1953):

1. Potential field equation governing static gravity, magnetic, and electrostatic fields, written as $\nabla^2 \phi = 0$, where the

Laplacian is written as $\nabla^2 \equiv \phi_{xx} + \phi_{yy} + \phi_{zz}$ in the Cartesian coordinate system.

2. Diffusion equation governing transport of heat, chemical concentration, low-frequency electromagnetism, stress diffusion in earthquake generation, groundwater flow, geomorphology, and many more, written as $\nabla^2 \phi = \partial \phi / \partial t$.
3. Wave phenomenon governing propagation of acoustic, elastic, and water waves due to sudden disturbances in the Earth system, written as $\nabla^2 \phi = \partial^2 \phi / \partial t^2$.

For time harmonic waves or fields, diffusion and wave equations are reduced to the Helmholtz equation $\nabla^2 \phi = -k^2 \phi$. PDEs describing mantle and core convection involved in quantifying plate tectonic processes and origin of the magnetic field are also reduced to the above elliptic, parabolic, and hyperbolic equations under various approximations of flow conditions likely to be met in Earth. For various problems in geoscience, these equations are written in the Cartesian, cylindrical, or spherical coordinates.

The above equations are supplemented by boundary and initial conditions to solve problems related to a vast area of geosciences. There are three kinds of boundary conditions, namely, the Dirichlet, the Neumann, and the Robin boundary conditions. These are:

- Dirichlet condition: ϕ is prescribed on the boundary.
- Neumann condition: $\nabla \phi$ is prescribed on the boundary.
- Robin condition: $a\phi + b\nabla \phi$ is prescribed on the boundary.

Mathematical investigations of the PDEs reveal that not all solutions of these equations may be useful for interpreting observations. Hadamard (1902) proposed a set of criteria which a well-posed problem should fulfill. These are as follows: (i) the solution should exist, (ii) the solution should be unique, and (iii) the solution should depend on the given data continuously, i.e., it should be stable. The equations should have proper initial and boundary conditions. Like for heat equation, we should have one initial condition along with

boundary conditions. And for second order wave equation we should have two initial conditions along with boundary conditions. Those problems which are not well posed in the sense of Hadamard criteria are called ill-posed problems. In some cases, solutions may not exist, for some it may not be unique, and for some others it may be unstable with respect to changes in given data. There are regularization methods to make such problems useful for interpreting data.

The basic strategy to solve PDEs is to split the problem into a series of initial value problems in ordinary differential equations (ODEs) (► [Ordinary Differential Equations](#)) or system of linear algebraic equations. For simple geometries in linear problems, the solution can be obtained by using well-known method of separation of variables, method of Green's function, and integral transform methods. For nonlinear and highly heterogenous problems, numerical methods such as finite difference or finite elements are used which involve ultimately solving a set of algebraic equations. These methods are briefly outlined below.

Method of Separation of Variables

This method is discussed here for the potential field equation in two-dimensional Cartesian coordinate system to describe temperature distribution, $T(x, z)$, in the crust. The domain extends in the horizontal (x) and vertical (z) directions as $-l \leq x \leq l$ and $0 \leq z \leq d$, respectively, with z positive downward. The PDE is written as

$$\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial z^2} = 0, \quad (2)$$

with the boundary conditions as

$$T(x, 0) = 0, T(x, d) = f(x), \quad (3a)$$

$$\frac{\partial T}{\partial y}(-l, z) = 0, \frac{\partial T}{\partial y}(l, z) = 0. \quad (3b)$$

Assuming that the variables are separable, the solution can be written as $T(x, y) = X(x)Z(z)$, which transforms Eq. 2 to a set of two ODEs:

$$\frac{1}{X} \frac{d^2 X}{dx^2} = -\frac{1}{Z} \frac{d^2 Z}{dz^2} = -\lambda^2, \quad (4)$$

with respective boundary conditions as

$$Z(0) = 0 = Z(d), \frac{dX}{dx}(-l) = 0 = \frac{dX}{dx}(l). \quad (5)$$

The solutions to this eigenvalue problem for X are orthogonal functions $X_n(x) = \cos(\lambda_n x)$, $\lambda_n = n\pi/l$, and the solution for Z satisfying boundary condition at $z = 0$ is $Z = \sinh(n\pi z/l)$. Therefore, the solution of T can be expressed as

$$T(x, y) = \sum_{n=0}^{\infty} c_n \cos(n\pi x/l) \sinh(n\pi z/l). \quad (6)$$

Applying boundary condition at $z = d$ yields

$$f(x) = \sum_{n=0}^{\infty} c_n \cos(n\pi x/l) \sinh(n\pi d/l). \quad (7)$$

Using the orthogonality property of $\sin(n\pi/l)$, we get expression for c_n as

$$c_n = \frac{2}{\sinh(n\pi d/l)} \int_0^d f(x) \cos(n\pi x/l). \quad (8)$$

Thus, for the given function $f(x)$, the solution can be obtained by evaluating this integral.

This method can also be applied to time-dependent heat conduction problem (κ – diffusivity) applied to cooling of a hot geological body, posed as

$$\frac{\partial T}{\partial t} - \kappa \frac{\partial^2 T}{\partial z^2} = 0, 0 \leq z < d, 0 \leq t < \infty. \quad (9)$$

The initial and boundary conditions are

$$T(z, 0) = f(z), \quad (10a)$$

$$u(0, t) = 0 = u(d, t). \quad (10b)$$

Using the method of separation of variables, we get two ordinary differential equations as

$$\frac{dT(t)}{dt} = -\kappa \lambda^2 T(t), \frac{d^2 Z(z)}{dz^2} = -\lambda^2 Z(z). \quad (11)$$

The differential equation for Z is posed as an eigenvalue problem with the solution $Z_n = \sin(\lambda_n z)$, where $\lambda_n = (n\pi/d)$. Thus, the solution is

$$u(z, t) = \sum_{n=1}^{\infty} C_n \sin\left(\frac{n\pi z}{d}\right) e^{-\lambda_n^2 \kappa t}. \quad (12)$$

The constants C_n are obtained by using the initial condition, which gives

$$u(z, 0) = f(z) = \sum_{n=1}^{\infty} C_n \sin\left(\frac{n\pi z}{d}\right). \quad (13)$$

Using the orthogonality of eigenfunctions, we get expression for constants C_n as

$$C_n = 2 \int_0^d f(x) \sin(n\pi z/d) dz. \quad (14)$$

Thus, the solution is given by

$$u(z, t) = 2 \sum_{n=1}^{\infty} \sin\left(\frac{n\pi z}{d}\right) \int_0^d f(z') \sin(n\pi z'/d) dz' e^{-\lambda_n^2 \kappa t}. \quad (15)$$

This method is also useful for solving wave equation problem posed as (here, u denotes displacement)

$$\frac{\partial^2 u}{\partial t^2} = \frac{1}{c^2} \frac{\partial^2 u}{\partial z^2}, 0 < t < \infty, 0 \leq z \leq d, \quad (16a)$$

$$u(0, t) = 0 = u(d, t), \quad (16b)$$

$$u(x, 0) = f(x), \frac{\partial u}{\partial t}(x, 0) = g(x). \quad (16c)$$

Using the method of separation of variables, $u = T(t)Z(z)$, two ordinary differential equations are

$$\frac{d^2 T(t)}{dt^2} = -\lambda^2 c^2 T(t), \frac{d^2 Z(z)}{dz^2} = -\lambda^2 Z(z), Z(0) = 0 = Z(d). \quad (17)$$

The differential equation for Z poses an eigenvalue problem with the solution $Z_n = \sin(\lambda_n z)$, where $\lambda_n = (n\pi/d)$. The solution of the PDE (Eq. 16a) is

$$u(z, t) = \sum_{n=1}^{\infty} \sin\left(\frac{n\pi z}{d}\right) \left(C_n \sin\left(\frac{n\pi c t}{d}\right) + D_n \cos\left(\frac{n\pi c t}{d}\right) \right). \quad (18)$$

Constants C_n, D_n are found by using the orthogonality property of the eigenfunctions, i.e.,

$$C_n = \frac{1}{d} \int_0^d f(z) \sin\left(\frac{n\pi z}{d}\right), \quad (19)$$

$$D_n = \frac{1}{n\pi c} \int_0^d g(z) \sin\left(\frac{n\pi z}{d}\right). \quad (20)$$

For given values of $f(z), g(z)$, we can get the values of these constants.

We have presented solutions in the Cartesian geometry. However, many problems in seismology and geomagnetism need spherical model of Earth. In such cases, the governing equation is written in the spherical coordinate system. Separated ODEs made use of special functions like spherical harmonics for latitude and longitude dependencies and Bessel functions to represent radial variations.

Method of Eigenvalue: Eigenfunction Expansion

This method can be used to solve more general heat/chemical/stress diffusion problems with inhomogeneous source and boundary conditions, such as

$$\frac{\partial T}{\partial t} = \kappa \frac{\partial^2 T}{\partial z^2} + g(z, t), 0 < t < \infty, 0 \leq z \leq d, \quad (21a)$$

$$T(0, t) = a(t), T(d, t) = b(t), T(z, 0) = f(z). \quad (21b)$$

The solution is written in two parts such that the boundary conditions become homogeneous, i.e.,

$$T(z, t) = u(z, t) + v(z, t). \quad (22)$$

The function $v(z, t)$ is chosen as $v(z, t) = a(t) + z(b(t) - a(t))/d$ so that the equation for $u(z, t)$ becomes

$$\frac{\partial u}{\partial t} = \kappa \frac{\partial^2 u}{\partial z^2} + g'(x, t), 0 < t < \infty, 0 \leq z \leq d, \quad (23)$$

where $g'(z, t) = g(z, t) - \partial v/\partial t$. The boundary and initial conditions of $u(z, t)$ become $u(0, t) = 0 = u(d, t)$ and $u(z, 0) = f(x) - v(z, 0)$, respectively.

The solution for $u(z, t)$ is thus obtained by using the following eigenvalues and eigenfunctions (► [Eigenvalues and Eigenvectors](#)):

$$\lambda_n = \left(\frac{n\pi}{d}\right), u_n = \sin(\lambda_n z). \quad (24)$$

The method described for wave equation in previous section can be followed to get the solution:

$$T(z, t) = v(z, t) + \sum_{i=1}^n \left(\int_0^d e^{\kappa \lambda_n^2 (t-\tau)} g'_n(\tau) d\tau + e^{\kappa \lambda_n^2 t} T_n(0) \right) \sin \lambda_n z. \quad (25)$$

Here, $T_n(0)$ is given by

$$T_n(0) = \frac{2}{d} \int_0^d (f(x) - v(z, 0)) \sin(\lambda_n z) dz. \quad (26)$$

The above formulation used the Dirichlet boundary condition. Similar approach can be used to find solution for the Neumann and the Robin boundary conditions.

The above formulation can also help in solving following more general advection-diffusion equation which occurs in several transport processes like heat, groundwater flow (► [Flow in Porous Media](#)), and dispersion of chemical substance in the underground:

$$\frac{\partial T}{\partial t} + v \frac{\partial T}{\partial z} = \kappa \frac{\partial^2 T}{\partial z^2}, \quad (27a)$$

$$T(0, t) = 0, T(d, t) = 0, T(x, 0) = f(z). \quad (27b)$$

We can use the following transformation to the variable $T(z, t)$

$$T(z, t) = T'(z, t) e^{ax+bt}, \quad (28)$$

to get

$$\frac{\partial T'}{\partial t} + (b + va - a^2\kappa) \kappa T' + (v - 2a\kappa) \frac{\partial T'}{\partial z} = \kappa \frac{\partial^2 T'}{\partial z^2}. \quad (29)$$

We assume $b + va - a^2\kappa = 0$ and $v - 2a\kappa = 0$, which gives $a = v/2\kappa$ and $b = -v^2/4\kappa$. With this, advection diffusion and initial/boundary conditions reduce to

$$\frac{\partial T'}{\partial t} = \kappa \frac{\partial^2 T'}{\partial z^2}, \quad (30a)$$

$$T'(0, t) = 0, T'(d, t) = 0, T(x, 0) = f(z) e^{-vx/2\kappa}. \quad (30b)$$

This can then be solved by using eigenvalue-eigenvector expansion method discussed above.

Method of Integral Transforms

Integral transforms reduce PDEs to ODEs. The choice of integral transforms depends on the nature of boundary condition. A popular method for solving time-dependent problems is the Laplace transform method (► [Laplace Transform](#)). Laplace transform method, in respect of time $0 < t < \infty$, is defined as

$$T(z, p) = L \{T(z, t)\} = \int_0^\infty e^{-pt} T(z, t) dt, \quad (31)$$

with the inverse Laplace transform given by

$$T(z, t) = L^{-1} T(z, p) = \frac{1}{2\pi i} \int_{\sigma - i\epsilon}^{\sigma + i\epsilon} e^{pt} T(z, p) dp; \operatorname{Re}(p) = \sigma. \quad (32)$$

For a large number of functions, Laplace transform pairs have been obtained over the years and are well tabulated. We illustrate this method by estimating the temperature in half-space for prescribed initial condition, posed as

$$\frac{\partial T}{\partial t} - \kappa \frac{\partial^2 T}{\partial z^2} = 0, 0 < z < \infty, 0 < t < \infty, \quad (33a)$$

$$T(z, 0) = A, T(0, t) = 0. \quad (33b)$$

Taking Laplace transform of Eq. 33a, we get

$$pT(z, p) - A = \kappa \frac{d^2 T(z, p)}{dz^2}, \quad (34)$$

the solution of which is

$$T(z, p) = \left(C e^{z\sqrt{\frac{p}{\kappa}}} + D e^{-z\sqrt{\frac{p}{\kappa}}} \right) + \frac{A}{p}. \quad (35)$$

As the solution needs to be finite as z tends to infinity, the solution takes the form as

$$T(z, p) = \left(D e^{-z\sqrt{\frac{p}{\kappa}}} \right) + \frac{A}{p}. \quad (36)$$

The value of D is found by using surface boundary condition as $D = -A/p$. Thus, the solution in transform domain is

$$T(z, p) = \frac{A}{p} \left(1 - e^{-z\sqrt{\frac{p}{\kappa}}} \right). \quad (37)$$

The solution in time domain is obtained by performing inverse Laplace transformation. The solution is

$$T(z, t) = A \left(1 - \operatorname{erfc} \left(\frac{z}{\sqrt{4\kappa t}} \right) \right). \quad (38)$$

Similarly, Laplace transform can be used to solve first-order PDE occurring in geomorphology, h , representing elevation in river long profile under uplift denoted by b (► [Earth-Surface Processes](#)):

$$a \frac{\partial h}{\partial x} + \frac{\partial h}{\partial t} = b, 0 < t < \infty, 0 < x < \infty, \quad (39a)$$

$$h(x, 0) = 0, h(0, t) = 0. \quad (39b)$$

Taking Laplace transform of this equation, we get

$$a \frac{dh(x, p)}{dx} + ph(x, p) = b/p. \quad (40)$$

The solution of the equation is

$$h = \frac{b}{ap} + Ce^{-xp/a}. \quad (41)$$

Using the boundary condition, we get $C = -b/(ap)$, and the solution in transform domain is

$$h(x, p) = \frac{b}{ap} (1 - e^{-xp/a}) = \frac{b}{a} \left(\frac{1}{p} - \frac{e^{-xp/a}}{p} \right). \quad (42)$$

Taking inverse Laplace transformation, we get

$$h(x, t) = \frac{b}{a} (1 - H(t - x/a)). \quad (43)$$

There is a large class of integral transforms and their inverse, and these have been tabulated. Some of these transforms are (Carslaw and Jaeger 1959):

$$\text{Fourier } (-\infty < x < \infty) : F(k) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} f(x) e^{-ikx} dx$$

$$\text{Inverse Fourier} : f(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} F(k) e^{-ikx} dk$$

$$\text{Fourier sine } (0 < x < \infty) : F(k) = \frac{2}{\pi} \int_0^{\infty} f(x) \sin(kx) dx;$$

Dirichlet boundary condition

$$\text{Inverse Fourier sine} : f(k) = \int_0^{\infty} F(k) \sin(kx) dx$$

$$\text{Fourier cosine } (0 < x < \infty) : F(k) = \frac{2}{\pi} \int_0^{\infty} f(x) \cos(kx) dx;$$

Neumann boundary condition

$$\text{Inverse Fourier cosine} : f(k) = \int_0^{\infty} F(k) \sin(kx) dx$$

$$\text{Finite sine } (0 < x < L) : F_n = \frac{2}{\pi} \int_0^L f(x) \sin(n\pi x/L) dx;$$

Dirichlet boundary condition

$$\text{Inverse finite sine } (0 < x < L) : f(x) = \sum_{n=1}^{\infty} F_n \sin(n\pi x/L)$$

$$\text{Finite cosine } (0 < x < L) : F_n = \frac{2}{\pi} \int_0^L f(x) \cos(n\pi x/L) dx;$$

Neumann boundary condition

$$\text{Inverse finite cosine } (0 < x < L) : f(x)$$

$$= \frac{F_0}{2} + \sum_{n=1}^{\infty} F_n \cos(n\pi x/L)$$

These transforms are helpful in solving PDEs with applicable boundary conditions.

Green's Function Approach

Green's function arises in geoscience problems when attention is focused on generation of fields by sources. For example, in case of earthquakes, the generated displace field $\mathbf{u}$, expressed in terms of potential ϕ as $\mathbf{u} = \nabla \phi$, due to seismic sources $f(r, t)$, can be obtained by solving (Aki and Richards 2002)

$$\nabla^2 \phi - \frac{1}{\alpha^2} \frac{\partial^2 \phi}{\partial t^2} = -f(r, t). \quad (44)$$

Green's function, $G(r, t, r_0, t_0)$, corresponding to the above problem is given by the solution of

$$\nabla^2 G - \frac{1}{\alpha^2} \frac{\partial^2 G}{\partial t^2} = -\delta(r - r_0) \delta(t - t_0), \quad (45)$$

representing point and instantaneous source. Taking Fourier transform (► [Fourier Transform](#)) of this equation, we get

$$(\nabla^2 + k^2) \bar{G} = \delta(r - r_0) e^{i\omega t_0}. \quad (46)$$

The solution of this equation, which decays to zero as $r \rightarrow \infty$, is

$$\bar{G} = -\frac{e^{-ik|r-r_0|}}{4\pi|r-r_0|} e^{i\omega t_0}. \quad (47)$$

Taking inverse Fourier transform, we get

$$G = \frac{-\delta(t - t_0 - \frac{r-r_0}{c})}{4\pi|r-r_0|}. \quad (48)$$

Knowing Green's function solution, the solution of Eq. 44 is obtained by integrating Green's function over volume, i.e.,

$$\phi(r, t) = \int G(r, r_0, t, t_0) f(r_0, t_0) dr_0 dt_0. \quad (49)$$

Thus, the displacement field can be constructed for any given source.

Method of Characteristics for Wave Equations

The method of characteristics also reduces a PDE into a set of ODEs. This is demonstrated by the following equation describing erosion due to stream power in geomorphology (► [Earth-Surface Processes](#)) in the presence of tectonic uplift:

$$a \frac{\partial h}{\partial x} + b \frac{\partial h}{\partial t} = c, h(0) = f(x). \quad (50)$$

This PDE is equivalent to the following three ODEs, called characteristic and compatibility equations:

$$\frac{dx}{ds} = a, \frac{dt}{ds} = b, \frac{dh}{ds} = c. \quad (51)$$

The initial conditions for these equations at $s = 0$ are, η being parameter along x -axis,

$$x = x_0(\eta), t = t_0(\eta), h = h_0(\eta). \quad (52)$$

We also have $t = 0, x = \eta, h = f(\eta)$. Thus, the solutions of characteristic curves are, a, b , and c being constants,

$$x = as + \eta, t = bs, h = cs + f(\eta). \quad (53)$$

Transforming in the original domain, we get solution as

$$h(x, t) = ct/b + f(x - at/b). \quad (54)$$

This can be extended to initial and boundary value problems.

Ray Method in Wave Propagation

Seismological knowledge is built on using the solution of wave equation in interpreting earthquake data. The most commonly used solution is ray solution of wave equation (Aki and Richards 2002). For time harmonic waves ($\phi = \phi' e^{-i\omega t}$), the wave equation reduces to

$$\nabla^2 \phi' = \frac{(-i\omega)^2}{\alpha^2} \phi'. \quad (55)$$

High-frequency waves propagate along rays. In this, the solution is sought in the following form:

$$\phi' = A(x) e^{-i\omega B(x)}. \quad (56)$$

Substituting in the wave equation, we get

$$\nabla^2 A - w^2 A |\nabla B|^2 - i(2w \nabla A \cdot \nabla B + w A \nabla^2 B) = -\frac{w^2}{\alpha^2} A. \quad (57)$$

By separating real and imaginary parts, we get the following two equations:

$$\nabla^2 A - w^2 A |\nabla B|^2 + \frac{w^2}{\alpha^2} A = 0, \quad (58a)$$

$$2w \nabla A \cdot \nabla B + w A \nabla^2 B = 0. \quad (59b)$$

The real part is rewritten as

$$\frac{1}{Aw^2} \nabla^2 A - |\nabla B|^2 + \frac{1}{\alpha^2} = 0. \quad (60)$$

In high-frequency situation, the first term can be ignored to get the eikonal or ray equation:

$$|\nabla B|^2 = \frac{1}{\alpha^2} = n^2. \quad (61)$$

The reciprocal of velocity, denoted by n , is called the slowness parameter. Wavefront is given by $B = \text{constant}$. Ray path is given by ∇B . This is a first-order hyperbolic equation and can be solved by using the method of characteristics. A simple solution is

$$A = 1, B = nx. \quad (62)$$

Thus, we get plane wave solution as

$$\phi = e^{-i\omega(nx+t)}. \quad (63)$$

The imaginary part gives transport equation as

$$2\nabla A \cdot \nabla B + A \nabla^2 B = 0. \quad (64)$$

This equation is used to find the amplitude of the propagating waves.

Similarity Solutions

It is possible to transform PDE into ODE by symmetry transformations. Following dilation, symmetry transformation gives the so-called similarity solution:

$$x' = \frac{x}{L}, t' = t/L^\beta. \quad (65)$$

In case of heat diffusion problem

$$\frac{\partial T}{\partial t} - \kappa \frac{\partial^2 T}{\partial z^2} = 0, 0 < z < \infty, 0 < t < \infty, \quad (66a)$$

$$T(z, 0) = T_m, T(0, t) = T_0, \quad (66b)$$

a similarity parameter $\eta = z/2\sqrt{\kappa t}$ is defined such that the diffusion equation reduces to

$$\frac{d^2 T}{d\eta^2} + 2\eta \frac{dT}{d\eta} = 0. \quad (67)$$

To set up boundary condition, temperature is also made nondimensional by using $T' = (T - T_m)/(T_m - T_0)$ such that

$$T'(0) = 1, T'(\infty) = 0. \quad (68)$$

The solution is obtained in terms of the error function as

$$T' = 1 - \text{erf}(\eta), \text{ where } \text{erf}(\eta) = \frac{2}{\sqrt{\pi}} \int_0^\eta e^{-y^2} dy. \quad (69)$$

This solution is used in quantifying the heat flow, bathymetry, seismicity, and many other aspects of structure and evolution of the oceanic lithosphere (Turcotte and Schubert 2002).

Numerical Methods

Very few PDEs representing the real Earth situations have analytical solutions for the given geometry and distribution of properties. In these cases, recourse to numerical methods is taken (► [Computational Geosciences](#)). Numerical methods aim at approximating PDEs to a system of linear algebraic equations which can be solved iteratively. There are two main methods for solving PDEs numerically, finite difference and finite element. In finite difference method, the derivatives occurring in the equations are approximated by difference forms, with values of the variables at discrete nodes. This results in a set of algebraic equations. In the finite element method, whole geometry is divided into finite elements; such elements could be finite interval in 1D or triangle in 2D or tetrahedron in 3D. Within the elements, continuous variation of the variables is assumed in terms of their values on the nodes of the elements. PDE is written in variational form over the domain, and the equations in terms of nodal values are derived by integrating the variation

equation over the elements. This again results in a set of algebraic equations.

Finite Difference Method

Semi-Discrete Method

We illustrate this method on the following heat diffusion problem:

$$\frac{\partial T}{\partial t} - \kappa \frac{\partial^2 T}{\partial z^2} = g(z), 0 < z < d, 0 < t < \infty, \quad (70a)$$

$$T(z, 0) = f(z), T(0, t) = 0 = T(d, t). \quad (70b)$$

We discretize z -axis as $z_i = i\Delta z$, $i = 0, 1, 2, \dots, n + 1$; $\Delta z = d/(n + 1)$. On this grid, we have the following discrete form of the second space derived in the equation

$$\frac{\partial^2 T}{\partial z^2} \approx \frac{T(z_{i+1}, t) - 2T(z_i, t) + T(z_{i-1}, t))}{(\Delta z)^2}. \quad (71)$$

Thus, the governing equation is approximated as

$$\frac{dT_i}{dt} \approx \kappa \frac{T_{i+1} - 2T_i + T_{i-1}}{(\Delta z)^2} + g(z_i), i = 1, 2, 3 \dots n. \quad (72a)$$

$$T_i = T(z_i, t), T_0 = 0 = T_{n+1}, T_i(0) = f(z_i). \quad (72b)$$

These equations can be solved as a system of first-order ODEs.

Semi-Discrete Collocation Method

In this method, the space part of solution is written in terms of some basis functions (► [Radial Basis Functions](#)), $\phi_j(z) : j = 1, \dots, n$ as

$$T(z, t) \approx \sum_{j=1}^n a_j(t) \phi_j(z). \quad (73)$$

We substitute this expression in the governing equation and get

$$\begin{aligned} \sum_{j=1}^n a'_j(t) \phi_j(z_i) &= \kappa \sum_{i=1}^n a_j(t) \phi_j''(z_i) \\ &+ \sum_{i=1}^n g(z_i) \phi_j(z_i). \end{aligned} \quad (74)$$

This can be written in matrix form as

$$a' = \kappa M^{-1} N a + M^{-1} b. \quad (75)$$

Here $a = [a_1, a_2, \dots, a_n]^T$; $m_{ij} = \phi_j(z_i)$; $n_{ij} = \phi_j''(z_i)$; $b_{ij} = g(z_i)\phi_j(z_i)$. This is a system of ODEs which can be solved by following ODE solution methods.

Fully Discrete Methods

Here, both space and time domain are discretized. The time is discretized as $t_k = \Delta t$, $k = 1, 2, \dots$. Fully discrete form of the governing equation is

$$\frac{T(t_{k+1}, z_k) - T(t_k, z_k)}{\Delta t} \approx \kappa \frac{T(z_{l+1}, t_k) - 2T(z_i, t_k) + T(z_{l-1}, t_k)}{(\Delta z)^2} + g(z_i), \quad (76a)$$

$$\begin{aligned} T(t_{k+1}, z_k) = & T(t_k, z_k) \\ & + \frac{\kappa \Delta t}{(\Delta z)^2} (T(z_{l+1}, t_k) - 2T(z_i, t_k) + T(z_{l-1}, t_k)) \\ & + g(z_i) \Delta t. \end{aligned} \quad (76b)$$

The initial and boundary conditions are

$$T(z_i, 0) = f(z_i), T(0, t_k) = 0 = T(z_{n+1}, t_k). \quad (77)$$

This problem can be solved iteratively. This is called explicit method. The space and time steps are chosen so that the solution is stable. This requires meeting the Courant-Friedrichs-Lewy (CFL) criteria:

$$\frac{\kappa \Delta t}{(\Delta z)^2} \leq \frac{1}{2}. \quad (78)$$

Finite Element Method

The most useful method in FEM uses weak formulation of the problem. Weak solutions are applicable to geophysical situations for which classical solutions having smoothness and other regulatory condition are not applicable. In this case, the PDE is reduced to set of ODEs. Here, governing equation is multiplied by a test function and integrated over the whole domain. Thus, for one-dimensional heat diffusion equation, we get

$$\int_0^d v(z) \left(\frac{\partial T}{\partial t} - \kappa \frac{\partial^2 T}{\partial z^2} \right) dz = \int_0^d v(z) g(z) dz. \quad (79)$$

The second term on the right-hand side is integrated by parts, and using the boundary condition on the test function, we get

$$\int_0^d v(z) \frac{\partial T}{\partial t} dz + \kappa \int_0^d \frac{\partial v}{\partial z} \frac{\partial T}{\partial z} dz = \int_0^d v(z) g(z) dz. \quad (80)$$

To proceed further to get a set of ODEs, the solution is written in terms of orthogonal basis functions as

$$T(z, t) \approx \sum_{j=1}^n a_j(t) \phi_j(z). \quad (81)$$

The test function is also taken as

$$v(z) = \phi_i(z). \quad (82)$$

Substituting both in the integral expressions, we get

$$\begin{aligned} & \int_0^d \phi_i(z) \frac{\partial}{\partial t} \left(\sum_{j=1}^n a_j(t) \phi_j(z) \right) dz \\ & + \kappa \int_0^d \frac{\partial \phi_i(z)}{\partial z} \frac{\partial}{\partial z} \left(\sum_{j=1}^n a_j(t) \phi_j(z) \right) dz \\ & = \int_0^d \phi_i(z) g(z) dz. \end{aligned} \quad (83)$$

We denote

$$M_{ij} = \int_0^d \phi_i(z) \phi_j(z) dz, \quad (84a)$$

$$N_{ij} = \int_0^d \frac{\partial \phi_i(z)}{\partial z} \frac{\partial \phi_j(z)}{\partial z} dz, \quad (84b)$$

$$g_i = \int_0^d \phi_i(z) g(z) dz. \quad (84c)$$

We then get

$$M \frac{da}{dt} + Na = g. \quad (85)$$

The initial condition is obtained by using the orthogonality properties of ϕ_j

$$T(z, 0) = f(z) = \sum_{j=1}^n a_j(0) \phi_j(z). \quad (86)$$

These ODEs are solved to get the solution of the PDE.

Deep Learning Method

PDEs also are used in deep learning algorithms. Space-time observations are fitted to PDEs with unknown coefficients which are then determined by using an optimization process based on neural network ([► Neural Networks](#)). This then helps to know the nature of physical processes involved in

generating the observations. Deep learning methods (► [Machine Learning and Geosciences](#)) are also used to find the solution of PDEs by approximating the functions by neural networks. In one such method, called deep Galerkin method (Raissi 2018), the solution which in the FEM is approximated by certain basis functions is instead approximated by neural network. This method helps to solve faster when grids and basis functions become large in multi-dimensional geometries.

Summary

Most processes in geosciences vary with space and time. These processes are governed by conservation laws and constitutive relationships for various materials occurring in Earth. Combining these, we get laws of continuum physics written as partial differential equations. These equations are in general second-order partial differential equations. General strategy in solving these equations is to convert them into a set of ordinary differential equations by using the method of separation of variable, transformation methods, or numerical methods. We have presented these developments as applied to the study of processes related to the Earth.

Definition

One of the nature-inspired meta-heuristic global optimization methods, the particle swarm optimization (PSO), is here introduced and its application in geosciences presented. The basic algorithm with an illustrative example is discussed and compared with other global methods like simulated annealing, differential evolution, and Nelder-Mead method.

Global Optimization

In global optimization problems, where an objective function $f(x)$ having many local minima is considered, finding the global minimizer (also known as global solution or global optimum) x^* and the corresponding f^* value is of concern.

Global optimization problems arise frequently in engineering, decision-making, optimal control, etc. (Awange et al. 2018). There exist two huge but almost completely disjoint communities (i.e., they have different journals, different conferences, different test functions, etc.) solving these problems: (i) a broad community of practitioners using stochastic nature-inspired meta-heuristics and (ii) academicians studying deterministic mathematical programming methods.

To solve global optimization problems, where evaluation of the objective function is an expensive operation, one needs to construct an algorithm that is able to stop after a fixed number of evaluations M of $f(x)$, from which the lowest obtained value of $f(x)$ is used. For global optimization, it is not the dimension of the problem that is important in local optimization but rather the number of allowed function evaluations (often called budget). In other words, when one has the possibility to evaluate $f(x)$

M times (these evaluations are hereinafter called trials), in the global optimization problem of the dimension 5, 10, or 100, the quality of the found solution after M evaluations is crucial and not the dimensionality of $f(x)$. This happens because it is not possible to adequately explore the multidimensional search region D at this limited budget of expensive evaluations of $f(x)$. For instance, if $D \subset R_{20}$ is a hypercube, then it has 220 vertices. This means that one million of trials are not sufficient not only to explore well the whole region D but even to evaluate $f(x)$ at all vertices of D . Thus, the global optimization problem is frequently *NP-hard*.

Meta-heuristic algorithms widely used to solve real-life global optimization problems have a number of attractive properties that have ensured their success among engineers and practitioners. First, they have limpid nature-inspired interpretations explaining how these algorithms simulate behavior of populations of individuals. Other reasons that have led to a wide spread of meta-heuristics are the following: they do not require high level of mathematical preparation to understand them, their implementations are usually simple, and many codes are freely available. Finally, they do not need a lot of memory as they work at each moment with only a limited population of points in the search domain. On the flip side, meta-heuristics have some drawbacks, which include usually a high number of parameters to tune and the absence of rigorously proven global convergence conditions ensuring that sequences of trial points generated by these methods always converge to the global solution x^* . In fact, populations used by these methods can degenerate prematurely, returning only a locally optimal solution instead of a global one or even nonlocally optimal point if it has been obtained at one of the last evaluations of $f(x)$ and the budget of M evaluations has not allowed it to proceed with an improvement of the obtained solution.

Nature-Inspired Global Optimization

Meta-heuristic algorithms are based on natural phenomenon such as particle swarm optimization simulating fish schools or bird groups; firefly algorithm simulating the flashing behavior of the fireflies; artificial bee or ant colony representing a colony of bees or ants in searching the food sources; differential evolution and genetic algorithms simulating the evolution on a phenotype and genotype level, respectively; harmony search method that is inspired by the underlying principles of the musicians' improvisation of the harmony; black hole algorithm that is motivated by the black hole phenomenon, namely, if a star gets too close to the black hole, it will be swallowed by the black hole and is gone forever; immunized evolutionary programming where adaptive mutation and selection operations are based on adjustment of artificial immune system; and cuckoo search based on

the brood parasitism of some cuckoo species, along with Levy flights random walks, just to mention some of them.

Particle Swarm Optimization

The idea of the particle swarm optimization (PSO) was inspired by the social behavior of big groups of animals, like flocking and schooling patterns of birds and fish, and suggested in 1995 by Russell Eberhart and James Kennedy, (see in Yang 2010).

Let us imagine a flock of birds circling over an area where they can smell a hidden source of food. The one who is closest to the food chirps the loudest, and the other birds swing around in his/her direction. If any of the other circling birds comes closer to the target than the first, it chirps louder and the others veer over toward him/her. This tightening pattern continues until one of the birds happens to land upon the food. So the motion of the individuals of the group is influenced by the motion of their neighborhood (Fig. 1).

In the searching space, we define discrete points as individuals (particles) which are characterized by their position vector determining their data (fitness) values to be maximized (similar to fitness function) and their velocity vectors indicating how much the data value can change and a personal best value indicating the closest the particle's data has ever come to the optimal value (target value).

Let us consider a population of N individuals, where their location vectors are $\vec{p}_i$, the objective function to be maximized is $\mathcal{F}$, and the fitness of an individual is $\mathcal{F}(\vec{p}_i)$. These values measure the attraction of the individual, namely, the higher its fitness value, the more the followers in its neighborhood, which will follow its motion. The local velocity of the individual $\vec{v}_i$ will determine its new location after Δt time step.

The velocity value is calculated according to how far an individual's data is from the target. The further it is, the larger is the velocity value. In the bird example, the individuals furthest from the food would make an effort to keep up with the others by flying faster toward the best bird (the individual having the highest fitness value in the population).

Particle Swarm Optimization in Geosciences, Fig. 1 Birds are swarming

Each individual's personal best value only indicates the closest the particle's data has ever come to the target since the algorithm started.

The best bird value only changes when any particle's personal best value comes closer to the target than best bird value. Through each iteration of the algorithm, best bird value gradually moves closer and closer to the target until one of the particles reaches the target.

Definitions and Basic Algorithm

We can give the following somewhat simplified basic algorithm of the PSO:

1. Generate the position and velocity vectors of each particle randomly:

$$P = (\vec{p}_0, \dots, \vec{p}_i, \dots, \vec{p}_N) \text{ and } V = (\vec{v}_0, \dots, \vec{v}_i, \dots, \vec{v}_N).$$

2. Compute the fitness of the particle:

$$\mathcal{F}(P) = (\mathcal{F}(\vec{p}_0), \dots, \mathcal{F}(\vec{p}_i), \dots, \mathcal{F}(\vec{p}_N)).$$

3. Store and continuously update the position of each particle where its fitness has the highest value:

$$P = (\vec{p}_0^{\text{best}}, \dots, \vec{p}_i^{\text{best}}, \dots, \vec{p}_N^{\text{best}}).$$

4. Store and continuously update the position of the best particle where its fitness has the highest value (global best):

$$\vec{p}_g^{\text{best}} = \max_{\vec{p} \in P} (\mathcal{F}(\vec{p})).$$

5. Modify the velocity vectors of each particle considering its personal best and the global best:

$$\vec{v}_i^{\text{new}} = \vec{v}_i + \varphi_1 (\vec{p}_i^{\text{best}} - \vec{p}_i) + \varphi_2 (\vec{p}_g^{\text{best}} - \vec{p}_i) \quad \text{for } 1 \leq i \leq N$$

Remark: Coefficient φ_1 ensures escaping from local optimum, since the motion of a particle does not follow the boss blindly!

6. Update the positions ($\Delta t = 1$):

$$\vec{p}_i^{\text{new}} = \vec{p}_i + \vec{v}_i^{\text{new}} \quad \text{for } 1 \leq i \leq N.$$

7. Stop the algorithm if there is no improvement in the objective function during a certain number of iterations or the number of iterations exceeds the limit.

8. Go back to (2) and compute new fitness value with the new positions.

Illustrative Example

Let us demonstrate the algorithm with a 2D problem. Let us suppose that the local geoid can be described by the following function (see Fig. 2):

$$\begin{aligned} f(x, y) = & -\sqrt{(6+x)^2 + (-9+y)^2} - \\ & \sqrt{(-11+x)^2 + (-3+y)^2} - \sqrt{(11+x)^2 + (9+y)^2} + \\ & \frac{50 \sin \left[\frac{\sqrt{(6+x)^2 + (-9+y)^2}}{\sqrt{(6+x)^2 + (-9+y)^2}} \right]}{\sqrt{(6+x)^2 + (-9+y)^2}} + \\ & \frac{50 \sin \left[\frac{\sqrt{(-11+x)^2 + (-3+y)^2}}{\sqrt{(-11+x)^2 + (-3+y)^2}} \right]}{\sqrt{(-11+x)^2 + (-3+y)^2}} + \\ & \frac{50 \sin \left[\frac{\sqrt{(11+x)^2 + (9+y)^2}}{\sqrt{(11+x)^2 + (9+y)^2}} \right]}{\sqrt{(11+x)^2 + (9+y)^2}} \end{aligned}$$

The parameters to be initialized are

$N = 100$; (number of individuals),
 $\lambda = \{\{-20, 20\}, \{-20, 20\}\}$; (location ranges),
 $\mu = \{\{-0.1, 0.1\}, \{-0.1, 0.1\}\}$; (velocity ranges),
 $M = 300$; (number of iterations),
 $\varphi_1 = 0.2$; (local exploitation rate),
 $\varphi_2 = 2.0$; (global exploitation rate).

Particle Swarm Optimization in Geosciences, Fig. 2 The 2D objective function

Figure 3 shows the distribution of the individuals after 300 iterations, while Table 1 shows the results of different global methods.

Variants of PSO

Although particle swarm optimization (PSO) has demonstrated competitive performance in solving global optimization problems, it exhibits some limitations when dealing with optimization problems with high dimensionality and complex landscape.

Numerous variants of even a basic PSO algorithm are possible in an attempt to improve optimization performance. There are certain research trends; one is to make a hybrid optimization method using PSO combined with other optimizers such as the genetic algorithm.

Another research trend is to try and alleviate premature convergence (i.e., optimization stagnation), e.g., by reversing or perturbing the movement of the PSO particles. Another approach of dealing with premature convergence is the use of multiple swarms (multi-swarm optimization).

Another school of thought is that PSO should be simplified as much as possible without impairing its performance, leading to the parameters being easier to fine-tune such that they perform more consistently across different optimization problems.

Particle Swarm Optimization in Geosciences, Fig. 3 The population distribution after 300 iterations

Particle Swarm Optimization in Geosciences, Table 1 The result of different global methods

Method	x_{opt}	y_{opt}	f_{opt}
Particle swarm	-6.01717	9.06022	10.8406
Simulated annealing	-6.01717	9.06022	10.8406
Differential evolution	-11.0469	-9.07418	5.3015
Nelder-Mead	-11.0469	-9.07418	5.3015

Initialization of velocities may require extra inputs; however, PSO variant has been proposed that does not use velocity at all.

As the PSO equations given above work on real numbers, a commonly used method to solve discrete problems is to map the discrete search space to a continuous domain, to apply a classical PSO, and then to remap the result, for example, by just using rounded values.

In general, an important variant and strategy of global optimization is to employ global method to find the close neighborhood of the global optimum and then apply local method to improve the result (Paláncz 2021).

PSO Applications in Geosciences

In this section, some case studies are introduced to illustrate the applicability of PSO algorithm in geosciences.

Particle Swarm Optimization for GNSS Network Design

The global navigation satellite systems (GNSS) are increasingly becoming the official tool for establishing geodetic networks. In order to meet the established aims of a geodetic network, it has to be optimized, depending on some design criteria (Grafarend and Sansò 1985). Optimization of a GNSS network can be carried out by selecting baseline vectors from all of the probable baseline vectors that can be measured in a GNSS network. Classically, a GNSS network can be optimized using the trial and error method or analytical methods such as linear or nonlinear programming or in some cases by generalized or iterative generalized inverses. Optimization problems may also be solved by intelligent optimization techniques such as genetic algorithms (GAs), simulated annealing (SA), and particle swarm optimization (PSO) algorithms. The efficiency and the applicability of PSO were demonstrated using a GNSS network, which has been solved previously using a classical method. The result shows that the PSO is effective, improving efficiency by 19.2% over the classical method (Doma 2013).

GNSS Positioning Using PSO-RBF Estimation Model

Positioning solutions need to be more accurate, precise, and obtainable at minimal effort. The most frequently used method nowadays employs a GNSS receiver, sometimes supported by other sensors. Generally, GNSS suffer from signal perturbations (e.g., from the atmosphere, nearby structures) that produce biases on the measured pseudo-ranges. With a view to optimize the use of the satellite signals received, a positioning algorithm with pseudo-range error modeling with the contribution of an appropriate filtering process includes, e.g., extended Kalman filter (EKF) and Rao-Blackwellized filtering (RBWF), which are among the most widely used algorithms to predict errors and to filter

the high frequency noise. A new method of estimating the pseudo-range errors based on the PSO-RBF model is suggested by Jgouta and Nsiri (2017), which achieves an optimal training criterion. The PSO is used to optimize the parameters of neural networks with radial basis function (RBF) in their work. This model offers appropriate method to predict the GNSS corrections for accurate positioning, since it reduces the positioning errors at high velocities by more than 50% compared to the RBWF or EKF methods (Jgouta and Nsiri 2017).

Using PSO to Establish a Local Geometric Geoid Model

There exist a number of methods for approximating local geoid surfaces (i.e., equipotential surfaces approximating mean sea level) and studies carried out to determine local geoids. In Kao et al. (2017), the PSO method as a tool for modeling local geoid is presented and analyzed. The ellipsoidal heights (h), derived from GNSS observations, and known orthometric heights (H) from first-order leveling from benchmarks were first used to create local geometric geoid model. The PSO method was then used to convert ellipsoidal heights (h) into orthometric heights (H). The resulting values were compared to those obtained from spirit leveling and GNSS methods. The adopted PSO method improves the fitting of local geometric geoid by quadratic surface fitting method, which agrees with the known orthometric heights within ± 1.02 cm (Kao et al. 2017).

Application of PSO for Inversion of Residual Gravity Anomalies over Geological Bodies with Idealized Geometries

A global particle swarm optimization (GPSO) technique was developed and applied by Singh and Biswas (2016) to the inversion of residual gravity anomalies caused by buried bodies with simple geometry (spheres, horizontal, and vertical cylinders). Inversion parameters, such as density contrast of geometries, radius of body, depth of body, location of anomaly, and shape factor, were optimized. The GPSO algorithm was tested on noise-free synthetic data, synthetic data with 10% Gaussian noise, and five field examples from different parts of the world. This study shows that the GPSO method is able to determine all the model parameters accurately even when shape factor is allowed to change in the optimization problem. However, the shape was fixed a priori in order to obtain the most consistent appraisal of various model parameters. For synthetic data without noise or with 10% Gaussian noise, estimates of different parameters were very close to the actual model parameters. For the field examples, the inversion results showed excellent agreement with results from previous studies that used other inverse techniques. The computation time for the GPSO procedure was very short (less than 1 s) for a swarm size of less than 50. The advantage of the GPSO method is that it is extremely fast and

does not require assumptions about the shape of the source of the residual gravity anomaly (Singh and Biswas 2016).

Application of a PSO Algorithm for Determining Optimum Well Location and Type

Determining the optimum type and location of new wells is an essential component in the efficient development of oil and gas fields. The optimization problem is, however, demanding due to the potentially high dimension of the search space and the computational requirements associated with function evaluations, which, in this case, entail full reservoir simulations. In Onwunalu and Durlofsky (2010), the particle swarm optimization (PSO) algorithm is applied to determine optimal well type and location. Four example cases are considered that involve vertical, deviated, and dual-lateral wells and optimization over single and multiple reservoir realizations. For each case, both the PSO algorithm and the widely used genetic algorithm (GA) are applied to maximize net present value. Multiple runs of both algorithms are performed, and the results are averaged in order to achieve meaningful comparisons. It is shown that, on average, PSO outperforms GA in all cases considered, though the relative advantages of PSO vary from case to case (Onwunalu and Durlofsky 2010).

Introducing PSO to Invert Refraction Seismic Data

Seismic refraction method is a powerful geophysical technique in near surface study. In order to achieve reliable results, processing of refraction seismic data in particular inversion stage should be done accurately. In Poormirzaee et al. (2014), refraction travel times' inversion is considered using PSO algorithm. This algorithm, being a meta-heuristic optimization method, is used in many fields for geophysical data inversion, showing that the algorithm is powerful, fast, and easy. For efficiency evaluation, different synthetic models are inverted. Finally, PSO inversion code is investigated in a case study at a part of Tabriz City in northwest of Iran for hazard assessment, where the field dataset are inverted using the PSO code. The obtained model was compared to the geological information of the study area. The results emphasize the reliability of the PSO code to invert refraction seismic data with an acceptable misfit and convergence speed (Poormirzaee et al. 2014).

PSO Algorithm to Solve Geophysical Inverse Problems: Application to a 1D-DC Resistivity Case

The performance of the algorithms was first checked by Fernández-Martínez et al. (2010) using synthetic functions showing a degree of ill-posedness similar to that found in many geophysical inverse problems having their global minimum located on a very narrow flat valley or surrounded by multiple local minima. Finally, they present the application of these PSO algorithms to the analysis and solution of an inverse problem associated with seawater intrusion in a

coastal aquifer in southern Spain. PSO family members were successfully compared to other well-known global optimization algorithms (binary genetic algorithms and simulated annealing) in terms of their respective convergence curves and the seawater intrusion depth posterior histograms (Fernández-Martínez et al. 2010).

Anomaly Shape Inversion via Model Reduction and PSO

Most of the inverse problems in geophysical exploration consist of detecting, locating, and outlining the shape of geophysical anomalous bodies imbedded into a quasi-homogeneous background by analyzing their effects on the geophysical signature. The inversion algorithm that is currently in use creates very fine mesh in the model space to approximate the shapes and the values of the anomalous bodies and the geophysical structure of the geological background. This approach results in discrete inverse problems with a huge uncertainty space, and the common way of stabilizing the inversion consists of introducing a reference model (through prior information) to define the set of correctness of geophysical models. A different way of dealing with the high underdetermined character of these kinds of problems consists of solving the inverse problem using a low dimensional parameterization that provides an approximate solution of the anomaly via particle swarm optimization (PSO), e.g., Fernández-Muñiz et al. (2020). This method has been designed for anomaly detection in geological setups that correspond with this kind of problem. These authors show its application to synthetic and real cases in gravimetric inversion performing at the same time uncertainty analysis of the solution. The two different parameterizations for the geophysical anomalies (polygons and ellipses) show that similar results are obtained. This method outperforms the common least-squares method with regularization (Fernández-Muñiz et al. 2020).

One-Dimensional Forward Modeling in Direct Current (DC) Resistivity

One-dimensional forward modeling in direct current (DC) resistivity is actually computationally inexpensive, allowing the use of global optimization methods (GOMs) to solve 1.5 D inverse problems with flexibility in constraint incorporation. GOMs can support computational environments for quantitative interpretation in which the comparison of solutions incorporating different constraints is a way to infer characteristics of the actual subsurface resistivity distribution. To this end, the chosen GOM must be robust to changes in the cost function and also be computationally efficient. The performance of the classic versions of the simulated annealing (SA), genetic algorithm (GA), and particle swarm optimization (PSO) methods for solving the 1.5 D DC resistivity inverse problem was compared using synthetic and field

data by Barboza et al. (2018). The main results are as follows: (1) All methods reproduce synthetic models quite well; (2) PSO and GA are comparatively more robust to changes in the cost function than SA; (3) PSO first and GA second present the best computational performances, requiring less forwarding modeling than SA; and (4) GA gives higher performance than PSO and SA with respect to the final attained value of the cost function and its standard deviation. To put them into effective operation, the methods can be classified from easy to difficult in the order PSO, GA, and SA as a consequence of robustness to changes in the cost function and of the underlying simplicity of the associated equations. To exemplify a quantitative interpretation using GOMs, these solutions were compared with least-absolute and least-squares norms of the discrepancies derived from the lateral continuity constraints of the log-resistivity and layer depth as a manner of detecting faults. GOMs additionally provided the important benefit of furnishing not only the best solution but also a set of suboptimal quasi-solutions from which uncertainty analyses can be performed (Barboza et al. 2018).

Summary

This study investigated the particle swarm method, its variants, and their applications in geosciences, i.e., optimization of GNSS network, approximation of local geoid surface, inversion of residual gravity anomalies, determination of optimal well locations, inversion of refraction seismic data, and solution of geophysical inverse as well as modeling direct current resistivity.

Pattern

Uttam Kumar

Spatial Computing Laboratory, Center for Data Sciences,
International Institute of Information Technology Bangalore
(IIITB), Bangalore, Karnataka, India

Definition

Spatial data analysis and spatial data mining encompass techniques to find pattern, detect anomalies and test hypotheses from spatial data (Shekhar and Xiong 2008). Pattern denotes the way in which we see and interpret a behavior and present them, where the term behavior refers to a particular, objectively existing configuration of characteristics (Andrienko and Andrienko 2006). A pattern is a construct reflecting essential features of a behavior in a parsimonious manner, i.e., in a substantially shorter and simpler way than specifying every reference and the equivalent characteristics. In the context of data mining, a pattern is an expression E in a language L describing facts in a subset F_E of a set of facts F (dataset) so that E is simpler than the enumeration of all facts in F_E (Andrienko and Andrienko 2006). So, a pattern may reflect a combination of qualities, acts, tendencies, etc., forming a consistent or characteristic arrangement. A pattern results from observation or analysis, an image of a behavior showing how an observer might understand it, which is often subjective. Therefore, different observers understand the

same behavior differently and represent it by different patterns. It is also apparent that one observer may use different patterns to describe the same behavior.

Introduction

Geographic knowledge discovery finds novel and useful geospatial knowledge hidden in Big Data. This is a human-centered process involving many activities such as data cleaning, data reduction, and data mining through scalable techniques to extract patterns to form knowledge (Shekhar and Xiong 2008). In fact, the basis of data mining is to discover patterns occurring in the database, such as associations, classification models, sequential patterns, etc. (Han and Kamber 2006). Areas of machine learning such as recognition, classification, clustering, prediction, association mining, sequential pattern mining, etc. constitute pattern discovery. Recognition and classification are complementary functions because classification is concerned with establishing criteria that can be used to identify or distinguish patterns appearing in the data. These criteria can depend on representatives of each class to numeric parameters for measurement, to syntactical descriptions of key features. Recognition is the process by which tools are subsequently used to find a particular pattern within the data (Russ 2002). Clustering of data has wider applications in many domains, for example, spatial data clustering of remotely sensed images from space-borne satellites to identify various land use classes (see Fig. 1).

Pattern, Fig. 1 Clustering of pixels for different land use classes in multispectral data having 5 spectral bands

For efficient data mining, the evaluation of pattern interestingness is made as deep as possible into the mining process so as to confine the search to only the interesting patterns. Often, domain knowledge are used to guide the discovery process to facilitate concise pattern discovery at various levels of abstraction. Integrity constraints and business rules help in evaluating the interestingness of the discovered patterns (Han and Kamber 2006).

Data pattern can be mined from many different kinds of database such as data warehouse, relational database, transactional database, object-relational database, spatial database, time-series database, sequence database, text database, multimedia database, data streams, World Wide Web, etc. Patterns such as frequent itemsets, subsequences and substructures occur frequently in the data. For example, in a transactional dataset of a supermarket, frequent itemset refers to a set of items that frequently appear together (example, milk and bread), whereas a frequent occurring subsequence that customers may tend to purchase from an electronic retail shop are computer and printer followed by ink cartridges, which represents a sequential pattern. A substructure can refer to different structural forms such as graph, trees, lattice, etc. Mining these frequent patterns leads to the discovery of interesting associations and correlations within data (Han and Kamber 2006).

In the context of spatial data, a tessellation (or tiling) is often used as a way of partition of space into mutually exclusive cells that together make up the complete study space. These are used for vector-based representation to characterize geographic fields and objects through a regular pattern. Examples of two regular tessellations are shown in Fig. 2 that represent square and hexagonal cells. It is fascinating to see that in all regular tessellations, cells are of the same shape and size, and that the field attribute value assigned to a cell is associated with the entire area occupied by the cell. Square cell tessellation pattern is common because of their ease in geo-referencing. It is interesting to notice how tessellation represents different patterns for building topology (By 2004).

Pattern can be described by terms like radial, checkboard, etc. In the context of terrain data, pattern refers to the spatial arrangement of objects and implies the characteristic

repetition of certain forms or relationships. For example, land use types have specific characteristic patterns such as irrigation types, different types of housing in urban areas, rivers with tributaries, etc. as observed from satellite images. Therefore, pattern is normally used as an interpretation element in image analysis (Kerle et al. 2004).

Types of Patterns

Pattern can be expressed mathematically, through attributes or numbers such as pattern observed in the recorded summer temperature across a city. A pattern may be broadly classified into the following types:

- Association pattern – it means description of a set of references as a unified whole on the basis of similarity of their features (Andrienko and Andrienko 2006). This unification is based on identical or similar characteristics where the attribute values correspond to the references. For example, cities can be grouped together as a cluster based on their population, where population is a close characteristic. This idea can be extended to account for clustering based on multiple attributes such as a cluster of cities with similar male and similar female proportions or low male and high female proportions or high male and low female proportions, etc. Association patterns are supplemented with summary characteristics of a combination of references from the individual characteristics. Numeric characteristics are summarized by aggregation of individual attributes into a single feature such as mean and variance, etc.
- Arrangement pattern – this defines the way characteristics are arranged in certain order for which time can be a reference to signify increasing or decreasing trends (Andrienko and Andrienko 2006). Pattern may also mean stability. The pattern ordering may be random such as cities with increasing population or regular such as a chessboard with black and white boxes. Spatial trends occur in spatial locations that do not exhibit natural

Pattern, Fig. 2 Tessellation: pattern in a square and hexagonal cell representation

ordering, however, some parameters like directions and distances in space can be used for ordering.

- **Differentiation pattern** – here, references are united because they are different from the characteristics of other remaining references/neighborhood that may form another pattern (Andrienko and Andrienko 2006). For example, grouping of regions that have relatively higher traffic than the neighborhood in the northern part of a city. Likewise, similar regions with equal traffic density may also occur in other parts (south, east, west, etc.) of the city. In such examples, references are done on some characteristics along with differentiation operation. Differentiation is possible even in the absence of common references, where the reference may have different characteristics from the remaining reference set. Outlier (local or global) fall in this category, where local outliers differ significantly from their neighborhood and global outliers have references that differ from the entire reference set. A subset of references can also be differentiated from the remaining references because of higher variability of characteristics in one subset than in other references.
- **Compound pattern** – this type of pattern emerges when the summarization of data involves division of a reference set into parts and association of elements on the basis of similar features, resulting in a compound pattern that comprises several subpatterns (Andrienko and Andrienko 2006). In other words, when the distribution does not clearly show a spatial pattern or trend, it can be described as a combination of two or more patterns called compound pattern. For example, “*spatial autocorrelation states that locations that are close are more likely to have similar values than locations that are far apart*” involves distance as a reference set because the characteristics change gradually, i.e., the neighboring objects differ less than the distant objects. In such cases, it makes sense to describe a spatial trend as a compound pattern (combination of two patterns).
- **Distribution summary pattern** – this defines the notion of the distribution (variance) of characteristics over a reference set (Andrienko and Andrienko 2006). Statistical mean, median, quartiles, quantiles, percentiles and variance in different types of distributions are often used to summarize the data. For spatially referenced data, center, entropy, etc. are used to summarize the homogeneity or heterogeneity.
- **Patterns in spatio-temporal data** – spatio-temporal data refers to data that are varying in both space and time domain, i.e., data point moving over space and time, for example, traffic flow at different times on the road.

A spatio-temporal pattern characterizes the spatial relationships among a collection of spatial entities and the behavior of such relationships over time, therefore they are often

multifaceted. Spatial relationship is complex and diverse, i.e. for any pair of spatial entities, a variety of spatial relations exist such as directional, distance based, and topological that are often application specific. Evolving spatial clusters generate pattern which have large number of spatial entities that are similar to one another in the neighborhood. So, spatio-temporal patterns have large number of spatial and temporal relations while spatial clusters may be restricted to relationship based on distances between entities. Spatio-temporal pattern studies are widely used in traffic analysis, security systems, epidemic studies and disease control, etc. (Shekhar and Xiong 2008). Handling spatio-temporal dataset still remains a challenge.

In this context, movement patterns in spatio-temporal data refer to events expressed by a set of entities such as movement of humans, traffic jams, migration of birds, bird flock movement, etc. In these cases, a pattern starts and ends at certain times and may be constrained to a subset of space. In geoscience, pattern is used with various meanings conceptualized as salient movement of events in the geospatial context. Application areas of movement pattern in spatio-temporal data are animal behavior, human movement (for example, tracking humans through mobile phones, cameras, etc.) for traffic management, surveillance and security, in military, sport’s action analysis, etc. The challenge rests in relating movement patterns with the underlying space to answer where, when, and why the entities move the way they do. Therefore, patterns need to be conceptualized with the surroundings (Shekhar and Xiong 2008).

There are a few interesting points that naturally emerge as a result of the pattern analysis of Big Data. It is important to state that not all the patterns are interesting and only a small fraction of them are of interest to a user. So, what makes a pattern interesting? A pattern is interesting if it is easily understood, valid on new dataset with some degree of certainty, useful and novel. A pattern is also interesting if it validates a hypothesis that the user sought to confirm because an interesting pattern also characterizes information that will turn into knowledge. There are several objective measures of pattern interestingness which are based on the structure of discovered patterns. For example, an objective measure for association rules is support and confidence. Support represents the percentage of transactions from a database that the given rule satisfies while confidence assesses the degree of certainty of the detected association (Han and Kamber 2006).

Pattern in Geoscience

There has been several studies that use artificial intelligence based techniques to reduce the multitude of phenomenon in the natural environment into discrete manageable classes. This is because humans are very good at detecting pattern,

but relatively poor in distinguishing subtle brightness difference such as in pixel values (reflectance) in multispectral imageries. In general, the term pattern recognition is the act of taking in raw data and making an action based on the category of the pattern (Duda et al. 2000). In spatial data analysis, pattern recognition or classification is a method used widely by which labels are attached to data (pixels) in view of their spectral characteristics (of the remote-sensing data). This labeling is implemented by any classification algorithm such as maximum likelihood classifier, random forest, support vector machine, etc. that are trained beforehand to recognize pixels with spectral pattern and similarities to derive land use classes. The method of land use detection or recognition has proved to be efficient, objective and reproducible.

Fig. 3 shows the spatio-temporal pattern of land use, highlighting the phenomenon of urban sprawl of Bangalore City, India derived from time-series Landsat data using a machine-learning approach. The patterns of land use classes such as built-up (including buildings, concrete surfaces, paved roads, parking lots, etc.), vegetation (gardens, lawns, parks, forest, agriculture/horticulture farms, etc.), water bodies (lakes, ponds, etc.), and others class (including fallow land, barren land, rocks and play grounds with soil) are clearly distinguishable. The time-series plot shows the trend/pattern of the growth of urban areas and reduction in the area of vegetation and water bodies as depicted in Fig. 4. Note that the detailed land use statistics and accuracy assessment of the

time-series-classified images have not been discussed here. Such geospatial analysis is very useful in understanding the past and present scenario of a spatial area and helps to model the trend to predict the future urban growth in various directions and distances from the City Center.

Pattern analysis has been used in many studies such as discovering climate change pattern using spatio-temporal dataset, analyzing temporal trends in precipitation and temperature, assessing the spatial distribution of global vegetation cover, for multivariate spatial clustering and geovisualization, discovering pseudopatterns, etc. (Miller and Han 2009). There are other applications including spatio-temporal video data mining to analyze abnormal activity, target analysis, content-based video retrieval under spatiotemporal distribution, urban sprawl pattern analysis, urban temperature analysis, (Li et al. 2015), spatial point pattern analysis (Cressie 2015), etc.

Summary

Pattern refers to the spatial arrangement of objects and implies the characteristic repetition of certain forms or relationships. Here, different types of patterns were broadly discussed. As such, there are no rules for selecting a pattern for a given problem. Discovering an interesting and useful pattern is subjective, so patterns symbolizing important characteristics need to be explored. Common properties for a set of

Pattern, Fig. 3 Spatio-temporal pattern of the urban sprawl of Bangalore City, India

Pattern, Fig. 4 Trend of the spatio-temporal change in land use classes in Bangalore City, India

references are easy to find out, however, distinguishing properties are rather difficult to discover. Patterns need to be distinctive and relevant to the goals of the investigation related to an application. Aggregation at an appropriate level helps in avoiding noninteresting results from summary characteristics. The degree of variation of the characteristics pertaining to the references along with the outliers has to be considered. Finally, pattern depends on the purpose of the analysis, whether a precise specification of a subset is required or an allusion is sufficient.

Definition

Pattern refers to the rules governing the arrangement of physical events or occurrences in space and time. Depending on the dynamic or static nature of the events, patterns can be spatial, temporal, and spatio-temporal. Patterns can be identified from geoscientific datasets by visualization and mathematical techniques collectively known as pattern analysis. These techniques are chosen depending on the geospatial representation of the events, e.g., as discrete points, lines, and polygons, or as continuous field values (raster or images). Pattern analysis of single type of data (univariate) can indicate whether the events tend to occur close to (clustered) or away from (dispersed) each other, while multivariate pattern analysis can also reveal how the attributes of the events are inter-related.

Pattern Analysis in Geosciences

Geological entities (events) are represented as points, lines, polygonal vectors, and rasters defined by their spatial

coordinates and associated with single or multiple attributes. For instance, at regional scale, mineral deposits are considered as points, lineaments as lines, lithological units as polygons, and surface elevation as raster. The underlying processes and rules governing the occurrence of these geological events result in distinguishable patterns of inter-relationships between them. These patterns can be identified by well-established methods. Statistical pattern analysis techniques test the hypothesis that the observed events are a realization of a random process. Several instances of the process are generated by Monte Carlo simulations. If the observed pattern occurs within the simulation envelope, it represents complete spatial randomness (CSR). Deviations from randomness are indications of positive association (or clustering, i.e., events tend to occur close to each other) or negative association (or dispersion, i.e., events tend to occur away from each other) (Fig. 1). In this chapter, we review some of the pattern analysis approaches with examples of their application in geosciences.

Patterns Analysis in Univariate Data

A univariate point data is defined within a spatio-temporal framework as the presence or absence of an event at a given location and/or time. A spatial point pattern (SPP) X consists of two main components – a set of points with well-defined coordinates $x_i \in \mathcal{R}^2$ (2D cartographic coordinates) and an observation window, that is, a delimiting boundary within which the analysis is restricted. An SPP can be extended to include the time of occurrence of each event to generate a spatio-temporal point pattern (STPP) $\{(x_i, t_i)\}$. In this case, the observation window is bounded in space, $x \in [x_1, x_2]$, and time, $t \in [t_1, t_2]$.

There are several graphical and statistical methods for SPP analysis (Baddeley 2015). Graphical methods visually and quantitatively highlight the regions of heterogeneity in the

PP. The simplest approach divides the observation window into equal and contiguous blocks of any size and shape (quadrats). Clustering is inferred in a quadrat if it has higher number of points in relation to the other quadrats. Alternatively, in kernel smoothed density function (KSDF) techniques, the PP is convolved with a kernel (such as Gaussian) to estimate the probability of occurrence (intensity) of points at every location in the observation window. A constant intensity throughout the window implies a homogeneous point process. Spatially varying intensity could indicate either inhomogeneity or clustering.

Such inferences can be associated with a level of statistical significance by hypothesis testing methods. For example, a chi-square goodness-of-fit test compares the observed quadrat counts to that expected from a homogeneous point Poisson process to infer CSR. However, distance-based techniques are more widely used for statistical SPP analysis. These are based on estimating the frequency distribution of the distance r between the closest pairs of points (Baddeley 2015, Diggle 2013, Lisitsin 2015). The inter-event distance calculator, G-function, is given by:

$$G(r) = \frac{\sum_{i \neq j}^N \text{count}(\min \|x_i - x_j\| < r)}{N} \quad (1)$$

Here, the numerator calculates the number of points x_i whose nearest neighbor x_j is closer than the distance r . N is the total number of points. The point-to-event distance calculator, F-function, is given by:

$$F(r) = \frac{\sum_{i=1}^M \sum_{j=1}^N \text{count}(\min \|u_i - x_j\| < r)}{N} \quad (2)$$

It calculates the distances to the nearest event x_j from selected M arbitrary points u_i in the empty space. The F-function provides a measure of the shapes of the empty spaces between the point patterns and is particularly useful when the

Pattern Analysis, Fig. 1 Different categories of spatial patterns, where the events are represented as points

observation window is a concave polygon. The inter-event and point-to-event functions are combined into another summary statistic called the J-function given by:

$$J(r) = \frac{1 - G(r)}{1 - F(r)} \quad (3)$$

$J(r) = 1$ represents CSR. If the empty spaces are more (i.e., $F(r)$ is small) and the points are closer to each other (i.e., $G(r)$ is large), $J(r) < 1$ and the PP is clustered. Conversely, $J(r) > 1$ indicates dispersion.

G , F , and J are first-order distance functions, in that only the nearest points are considered. There are well-established multi-distance functions that consider multiple points at different distances from each other, such as the K-function (Baddeley 2015). These methods can be used for hypothesis testing by appropriately selecting the point processes such as homogeneous Poisson point process (for constant point intensity), inhomogeneous Poisson point process (for variable but predictable intensity), doubly stochastic Poisson process, or Cox process (if intensity is also random) (see ► “Point Pattern Statistics”). In general, border correction is necessary to account for censoring errors caused by restricting the PP analysis to within the boundary of an observation window.

Similar to SPP, STPP analysis aims at understanding the interaction among events (Diggle 2013) in terms of the degree of clustering, but in both space and time. Thus, SPP analysis methods can be extended to STPP analysis by adding the temporal coordinate. Statistical STPP analysis methods include the use of Knox’s statistic, scan statistics, and tests related to the nearest-neighbor distribution, and second-order properties of the point process expressed through the Ripley’s K-function for homogeneous and inhomogeneous spatio-temporal point processes.

An application of STPP analysis is the modeling of earthquake events, which are known to trigger aftershocks close to the epicenter and occurrence time of a high-magnitude earthquake. Shi et al. (2009) used STPP analysis to study the sequences of aftershocks of the Wenchuan earthquake of 2008. They found the aftershock events to be clustered within 60 km and 260 hours from the high-magnitude earthquake. Besides points, univariate analysis applied to single-band rasters identifies relationships between neighboring pixels (e.g., texture analysis, hydrological and terrain modeling) using image processing techniques.

Patterns in Multivariate Data

Different geological processes are intricately linked to one another. Therefore, it seldom suffices to independently analyze only the coordinates of events that are also associated with other geological information. If each point x_i in an

SPP/STPP is associated with a mark m , the set of the point-mark combinations $\{(x, m)\}$ describes a marked point pattern (MPP) (Ho and Stoyan 2008). In geoscience applications, the marks are typically real-valued attributes. In the previous example of earthquake analysis if each earthquake event is also associated with its magnitude, it describes a marked STPP.

The mark can be modeled as a spatially continuous random field Z . However, this model assumes marks and points to be mutually independent, thus inhibiting the pattern analysis of correlations between them. In contrast, density-dependent marked Cox processes allow the modeling of inter-relationships between the points and the marks (Stoyan et al. 1995; Ho and Stoyan 2008). Several MPP distance functions are extensions of SPP analysis, for example, the normalized mean product of marks of a pair of points separated by a distance r . Common MPP processes include log Gaussian Cox process, intensity-marked Cox process, and geostatistical model for preferential sampling (Ho and Stoyan 2008).

A special case of MPPs is when the marks are categorical. Consider n point datasets $X_1, X_2, \dots, X_n$ each containing objects having the same categorical mark. Irrespective of the mark, any two points in the union of the n datasets are defined as neighbors if the distance between them is less than a given distance r_0 . A co-location pattern is defined by an undirected connected graph with points representing nodes and edges representing the neighborhood relationships between them. Patterns are mined from the graph based on spatio-temporal topological constraints and defining proximity rules that associate the objects of X_i with those of X_j , $i \neq j$. These association rules are defined using interestingness measures such as participation ratio, prevalence, and confidence (Mamoulis 2008). An application of co-location analysis is in determining the association of water reservoirs with incidence of diseases.

Patterns between vector geometries can be identified using probabilistic approaches such as the Weights of Evidence (WofE) model based on Bayesian method (Agterberg et al. 1993). It involves quantification of spatial association (in terms of weights) between the targeted geometry (hypothesis) and the evidential geometry (evidence). Figure 2 shows an application of WofE to mineral prospectivity modeling, where the hypothesis to be predicted is the occurrence of mineral deposits (points) and the evidential features are faults (lines). Here, the spatial association between deposits and the presence/absence of faults is assessed by the estimation of posterior probabilities.

Patterns between points and their enclosing polygons can be identified using the SPP analysis techniques by defining the polygons as observation windows. Mamuse et al. (2010) applied distance-based PP analysis to the exploration of nickel sulfide deposits within prospective komatiites in Kalgoorlie terrane. Considering the terrane as observation window, the nickel sulfide deposits and komatiite bodies

Pattern Analysis, Fig. 2 WofE method for identifying distance of spatial association between points and lines by calculating contrast, that is, difference between the probability of deposits within the feature and probability of deposits outside the feature

(represented as points) were found to be clustered. However, considering the komatiites as observation windows, the deposits were found to be randomly distributed or dispersed. This observation was used to estimate the number of deposits in a komatiite body and to identify the spatial controls on nickel sulfide mineralization.

Pattern analysis of multivariate rasters includes evaluation of the correlation and covariance matrices, and cluster analysis. In these methods, the geoscientific information from co-located pixels of each raster band is concatenated to form a feature-vector representing the set of attributes at a given location (corresponding to the pixel). The superset of all feature-vectors extracted from the full raster is then analyzed in the feature-space (where the support axes represent the different variables rather than the spatio-temporal coordinates in the original dataspace) to identify patterns of inter-relationships between the different variables.

A diagnostic step for advanced multivariate analyses involves computation of a correlation matrix, which estimates the pair-wise correlation coefficients between the variables or a covariance matrix, which characterizes the monotonic trend between the variables (positive covariance indicates variations in the same direction, while negative covariance indicates inverse directional variations). These matrices are precursors for advanced multivariate analysis such as principal component analysis (PCA), which is based on eigenvalue decomposition of the covariance matrix. PCA is used for identifying geochemical patterns of anomalous elemental concentrations or alteration patterns indicating mineralization or bedrock lithology. Graphs of the PC loadings indicate that elements (variables) located in proximity in the PC plots are closely related in the geochemical domain (e.g., Filzmoser et al. 2009).

Clustering (e.g., k-means, Isodata) algorithms are also used for finding patterns in the feature-space. Its simplicity lies in the calculation of Euclidean distances between the feature-vectors and grouping them into clusters by their proximity. The identified clusters are mapped back to the corresponding geospatial domains. The actual calculations

are iterative for the identification of cluster centroids and grouping of pixels until the centroids have stabilized or the maximum number of iterations has been reached (see ► “Pattern Recognition”).

Summary and Conclusions

We have seen different types of spatial and spatio-temporal patterns and the techniques for analyzing them as univariate or multivariate data by graphical methods, pattern mining, statistical testing, and probabilistic modeling. Pattern analysis supports the understanding of the underlying physical processes that cause the occurrence of the events at a particular location and/or time. This capability finds interesting applications in geosciences such as (1) interpolation, that is, estimating the values of spatio-temporal variables where observed data is not available; (2) forecasting, that is, predicting occurrence of events; (3) modeling, that is, identifying the underlying processes responsible for the occurrence of the pattern; and (4) simulations, that is, virtual regeneration of physical reality.

Apart from the methods described in this chapter, there are several supervised, semi-supervised, and unsupervised techniques for identifying patterns in images (either single or multiband) and applying them to the automatic classification of geological entities. Recently, pattern analysis has been extended to pattern recognition which incorporates advanced machine learning techniques (such as artificial neural networks, self-organizing maps, convolutional networks), which enable mineralization-related pattern identification from input raster data (see ► “Machine Learning”).

Definition

Pattern classification is the automated grouping or labeling of samples based on features or patterns in a dataset (Bishop 2006; Duda et al. 2001).

Introduction

Pattern classification involves using the features present in a dataset to automatically label each test point using a machine

learning method. It is a supervised learning method, where a training dataset is used to train the model. The training dataset contains both the input data and the corresponding label for each data point. The trained model is then used to classify the test dataset using the input data to predict the corresponding label (Bishop 2006; Duda et al. 2001).

Pattern classification can be performed on any dataset that can be divided into a set number of classes, each with distinct features in the data. In the geosciences this can include lithofacies classification (Bhattacharya et al. 2016), material classification (Banchs and Rondon 2007), geological mapping (Cracknell et al. 2014), wireline log interpretation (Song et al. 2020), anomaly detection (Gonbadi et al. 2015), and lithology classification (Bressan et al. 2020). Many different data types can be used for the classification including geophysical logs (Bhattacharya et al. 2016; Bressan et al. 2020; Cracknell et al. 2014; Song et al. 2020), geochemical samples (Cracknell et al. 2014; Gonbadi et al. 2015), airborne geophysical data (Cracknell et al. 2014), and seismic surveys (Banchs and Rondon 2007).

Machine learning methods that can be used for classification include support vector machine (SVM) (Bhattacharya et al. 2016; Bressan et al. 2020; Gonbadi et al. 2015), neural networks (NN) (Banchs and Rondon 2007; Bhattacharya et al. 2016; Song et al. 2020), self-organizing maps (SOM) (Bhattacharya et al. 2016; Cracknell et al. 2014), random forests (RF) (Bressan et al. 2020; Cracknell et al. 2014; Gonbadi et al. 2015), boosting (Gonbadi et al. 2015), and decision trees (Bressan et al. 2020). The best method to apply varies between different applications.

NN, SVM, and RF and examples of their application are discussed below. SOMs were designed as an unsupervised learning method; however supervised learning versions have been developed for classification tasks (Bhattacharya et al. 2016; Cracknell et al. 2014; Lau et al. 2006). For more details on SOMs, please refer to the “SOM” entry in this encyclopedia.

Neural Networks

Neural networks (NN) are a popular method for data classification that was designed to mimic the way that the human brain processes information. NN typically contain at least three layers. The first is an input layer that takes the input data and passes it to the hidden layer. The hidden layer learns the relationships between the input variables, then passes weighted data patterns to the output function. This output layer then determines the output, which for classification problems is a label. Multiple hidden layers can be used for complicated problems. In training, a NN is initially assigned random weight coefficients for the hidden layer. Training data is then repeatedly fed through the network and the weight coefficients are modified until the difference between the

outputs and the desired classifications are minimized. Iterative back-propagation is often used for this learning step. When designing a NN there are numerous parameters that can be altered, such as the number of hidden layers, the number of nodes in each hidden layer, learning rate, damping coefficient, and the number of iterations used for learning (Bishop 2006; Bhattacharya et al. 2016; Duda et al. 2001). Many different variations of NN exist, with variations on how the layers are built and the method used for training common changes. More information can be found in the ► [“Artificial Neural Network”](#) entry.

Bhattacharya et al. (2016) apply several different machine learning methods to classify multiple mudstone lithofacies from each other and calcareous siltstone and limestone lithofacies from petrophysical well logs. One of the methods applied is a standard NN using a single hidden layer. For this case, the authors found that the best results were achieved using a SVM.

Banchs and Rondon (2007) apply a Hopfield neural network (HNN) to several example cases, classifying areas of high and low porosity, or areas of sand or shale, using seismic attributes as the input. In a HNN the nodes in the hidden layer are binary instead of weighted, so each node is either on or off.

Song et al. (2020) classified shapes in in wireline logs using recurrent neural networks (RNN). This involved identifying four basic log shapes in spontaneous potential log segments. RNNs use previous outputs as part of the input to recognize trends and larger features. This model used six layers including a layer of Long Short Term Memory (LSTM) units. The RNN model was found to outperform a standard NN as well as other machine learning techniques for this problem.

Support Vector Machine

Support Vector Machine (SVM) is a popular machine learning method that maps the input data to a higher dimensional space to increase the distance between data points from different classes. A hyperplane can then be used to divide the points into classes. Support vectors are the points that are on the edges of the classes, closest to the hyperplane. The distances between the support vectors represent the margin. A model with larger margins is considered to be more robust, and less likely to misclassify edge points (Bhattacharya et al. 2016; Bressan et al. 2020; Schölkopf et al. 2000).

A kernel function is used to describe the mapping between the input space and the new higher dimensional space. Possible kernels include linear, polynomial, radial basis function (RBF), and multilayer perceptron. This kernel is optimized using the training data to minimize the margin. While ideally there should be no misclassifications in the training data, perfect separation may be impossible due to overlapping

classes. In this case a small number of errors may be tolerated. While SVM is a binary classifier, it can be used for multi-class problems using either a one-vs-all or pairwise one-vs-one method (Bhattacharya et al. 2016; Bressan et al. 2020). More information can be found in the ► [“Support Vector Machines”](#) entry.

Bhattacharya et al. (2016) used SVM with RBF to classify multiple mudstone lithofacies from each other and calcareous siltstone and limestone lithofacies from petrophysical well logs. The authors found that in this case SVM performed better than both NN and SOM.

Bressan et al. (2020) used SVM to classify sedimentary well logs into four lithology groups based on seven geophysical logs. The authors found that the SVM method used produced poor results, and suggested that this was due to the log data not containing a highly defined pattern, and insufficient data for proper training. In comparison, RF performed well on this data.

Gonbadi et al. (2015) applied SVM with a RBF kernel to identify geochemical anomalies in a porphyry copper to target new exploration drilling. Despite testing using two different feature selection methods, the authors found that a boosting method (AdaBoost) was better suited to this problem.

Random Forest

Random forest (RF) is a pattern classification method that is based on an ensemble of decision trees (Breiman 2001). Each individual decision tree is created by independently splitting the data using sequential queries at each node. This splitting divides the tree into branches, with leaves (each resembling a class) at the end of each sub-branch. Each decision tree has a different set of rules. A classification prediction can then be calculated by averaging the results from all of these trees, combining many weak classifiers into a single strong classifier. As more trees are included in the RF the generalization error converges to a limit without overfitting. The generalization error depends on both the strength of the trees and the correlation between the trees (Breiman 2001; Gonbadi et al. 2015).

The generalization error and variance of the RF can be reduced using bagging and random selection of features. Bagging involves generating a random individual subset, with replacement, of the dataset to train each decision tree. The samples not used in the training are then used to estimate the generalization error. For each of these trees a set number of features are randomly chosen to use in the decision nodes. As this method does not overfit, it has been shown to perform well in classifications involving multisource and high-dimensional data (Cracknell et al. 2014; Gonbadi et al. 2015). More information can be found in the ► [“Random Forest”](#) and ► [“Decision Trees”](#) entries.

Cracknell et al. (2014) used RF to classify geophysical and geochemical data into 21 discrete lithological units. The data was from an area with known volcanic-hosted massive sulfide (VHMS) deposits where field mapping is difficult due to poor outcrops and thick vegetation. Comparing the RF map to the geological interpretation demonstrated that the RF map not only performed well, but also included additional details about the spatial distributions of key lithologies.

Bressan et al. (2020) applied RF to seven geophysical logs to classify sedimentary well logs into four lithology groups. Compared to SVM, decision tree and multilayer perceptron (MLP) methods, RF performed well on this data. In two of the three scenarios considered RF obtained the best results. RF also performed well in all scenarios for cross-validation.

Gonbadi et al. (2015) applied a RF with 350 trees to identify geochemical anomalies to identify the best targets for new exploration drilling in a porphyry copper region. RF was chosen because it does not assume that the variables have a normal distribution. However, the authors found that a boosting method (AdaBoost) was better suited to this problem.

Summary

Pattern classification involves using a machine learning method to automatically group or label samples based on features or patterns in a dataset. It is a supervised learning method, requiring a training dataset that contains both the input data and the corresponding label for each data point. The trained model can then be used to predict the classification of new samples. Many different classification methods can be used. Popular methods include NN, SVM, and RF. Pattern classification has been applied to problems such as lithology or material classification, geological mapping, wireline log interpretation, and anomaly detection.

Pattern Recognition

Rogério G. Negri

São Paulo State University (UNESP), Institute of Science and Technology (ICT), São José dos Campos, São Paulo, Brazil

Definition

Pattern recognition comprises a field of study regarding how machines and algorithms may recognize patterns and structures on data sets and making decisions about them.

Pattern recognition embraces a research area that focuses on problems of classification and object description. With multidisciplinary aspects, the pattern recognition studies interface with statistic, engineering, artificial intelligence, computer science, data mining, image and signal processing, etc. Typical examples of applications are automatic character recognition, medical diagnosis, bank customer profiles monitoring, and even the most recent issues like recommendations systems and face recognition.

Process Overview

A pattern recognition process is not limited to apply methods in data sets but also includes distinct stages from the problem formulation, data collection, and representation until classification, assessment, and interpretation. Figure 1 depicts a common pattern recognition workflow.

Pattern Recognition,
Fig. 1 Pattern recognition
 workflow overview

In a broad view, a “pattern” is usually represented by a vector whose components values stands for a specific attribute previously measured by a sensor. Waves captured from an acoustic system, the number of financial transactions in a period, the spectral responses registered by a digital camera, and the climatic variables at a specific instant are examples of patterns in practical situations.

Based on the observed data and aiming to simplify or identify non-obvious information about them, associations are made between each of these data to a specific class or group/cluster. This pattern-to-class association process is called *classification*, which demands the modeling (i.e., choosing a model and respective parameterization) of a rule able to perform such a task.

As an intermediate part of this process, it needs to highlight the data preprocessing and assessment of the classification results. Computing additional values from the objects to provide a better description leads to a different stage known as “feature extraction.” Regarding all the available information, it is essential to use only the meaningful attributes in the pattern recognition process that favors error reduction and accuracy improvement. To do so, a careful “feature selection” is usually performed. Also, computing the error/accuracy levels should be systematically and persistently carried in an “assessment” stage.

Learning Paradigms

According to the previous discussions, a pattern recognition process lies in modeling a decision rule that can classify patterns regarding classes or clusters. The learning paradigm is directly related to how the modeling is carried.

Among different paradigms in the literature, the supervised, unsupervised, and semi-supervised are the most common. However, it is valid to mention other paradigms, for example, reinforcement, evolutionary, and instance-based learning.

The main characteristic that distinguishes supervised and unsupervised learning refers to how the classification rules are modeled. While supervised learning builds a model using information from a set of ground-truth examples in which the expected response is known (i.e., the class), unsupervised learning is based on similarities identified over the set of patterns without information about presumed classes. Examples whose response/class is known are called “labeled

patterns.” The set of labeled patterns required by supervised methods is defined as “training set.”

When the classes comprised by the classification are previously defined, supervised learning is preferable. However, insufficiently labeled data availability may turn unfeasible a supervised training. In this case, unsupervised learning rises as an alternative. Nonetheless, it should stress that results based on such a learning paradigm are restricted to groups/clusters of similar patterns without assigning them to a class.

These limitations became a starting point to the development of the semi-supervised paradigm, usually defined as a midterm between supervised and unsupervised, since it simultaneously uses labeled and unlabeled patterns to model the classification rules (Chapelle et al. 2006).

Approaches

Beyond the learning paradigm, the pattern recognition methods are also characterized according to the approach used to define the decision rules. Examples of approaches comprise template matching, statistical models (parametric or non-parametric), construction of decision surfaces based on geometric/structural criteria, and neural networks.

Template matching involves comparing and identifying similarities between patterns taken as referential (i.e., the templates) and other patterns whose class is unknown (Pavlidis 2013). This process should be independent of scale, rotation, and translation changes.

The statistical approach establishes decision regions using probability distributions representing each class included in the classification problem (Webb and Copsey 2011). The Bayes decision theory is an essential mathematical referential to define the rules and make decisions. Naive Bayes, maximum likelihood classification, and *K*-nearest neighbors are examples of statistical approach methods.

Methods with a geometric/structural approach are characterized by decision rules expressed by separation hyperplane or partitions in the attribute space (Bishop 2006). Support vector machines, decision trees, graph-based models, and the *K*-means algorithm follows the geometric/structural approach.

Lastly, methods based on the neural network approach simulate an arrangement of neurons that adapt to solve complex tasks with nonlinear input and outputs (Haykin 2009). Among many neural networks proposed in the literature, the multilayer perceptron, self-organizing maps, and convolutive neural networks are popular.

In addition, it is worth highlighting the possibility of combining the cited approaches into an ensemble scheme (Theodoridis and Koutroumbas 2008). Methods like AdaBoost and random forest are examples of ensembles widely adopted.

Applications in the Geosciences

Several studies and applications in geosciences employ pattern recognition concepts. Examples include seismic analysis, meteorology, land use and land cover mapping, and natural disaster prevention.

Curilem et al. (2016) use pattern recognition methods to extract features from seismic signals and build a system for volcanic events classification. Chattopadhyay et al. (2020) demonstrate that the integration of clustering and neural network concepts provides a potential method for weather pattern forecasting. Extreme rainfall forecasting using pattern recognition is another topic of relevance discussed in Nayak and Ghosh (2013). Distinctly, as proposed in Wang et al. (2015), an approach based on the support vector machine method allows reconstructing the historical data of weather type, which comprises an essential component for photovoltaic power forecasting. Mapping the land use and land cover is another topic of extreme relevance in several applications related to the geosciences (Giri 2012).

Summary

Pattern recognition comprises a research area focused on developing and applying mathematical and computational concepts to solve data classification problems. The amount and variety of pattern recognition applications in geosciences are vast.

Pawlowsky-Glahn, Vera

Ricardo A. Olea
Geology, Energy and Minerals Science Center,
U.S. Geological Survey, Reston, VA, USA

Fig.1 Vera Pawlowsky-Glahn, courtesy of Prof. Juan José Egozcue

Biography

Vera met her professional destiny the day she had a meeting with her adviser Wolfdietrich Skala to choose the topic of her dissertation. He offered her a job as collaborator on a compositional data analysis project, but she wanted to work on geostatistics. Vera first proved that spurious correlation was a

problem in both disciplines. The rest is history. Vera started a long spatiotemporal trek that took her to the top specialist on each discipline: Georges Matheron in France and Aitchison in Hong Kong. Progress toward the solution to the mapping of compositional data came in several installments. First was her dissertation (Pawlowsky 1986), then a translation with a few new developments (Pawlowsky-Glahn and Olea 2004) and finally the complete solution to the problem via the formulation of the Aitchison geometry (Pawlowsky-Glahn and Egozcue 2001). Over the years, in cooperation with multiple scientists around the world, Vera expanded her interest to all aspects of compositional modeling, writing more than 100 papers. The main accomplishments of her career are summarized in Pawlowsky-Glahn et al. (2015). Without Vera, Aitchison's ideas may have been lost or, at best, it would have taken much longer to receive the acceptance that they have today. The compositional data specialists around the world prepared a Festschrift (Filzmoser et al, 2021) in appreciation for Vera's contribution to the field.

Upon finishing graduate school, Vera spent her career with the Polytechnical University in Barcelona (1986–2000), serving as Associate Professor, and with the University of Girona (2000–2018), where she reached the position of Chair of the Computer Sciences, Applied Mathematics and Statistics Department. Vera has been quite active in the International Association for Mathematical Geosciences (IAMG), organizing the third IAMG conference in 1997, serving as chair of several committees, convener of numerous sessions, the 2007 Distinguished Lecturer, and the 11th President (2008–2012). IAMG presented her with the 2006 Krumbein Medal for her valuable contributions to science, the profession and IAMG, and also the 2008 Cedric Griffiths Teaching Award. She was instrumental in starting the Compositional Data Association in 2015, serving as the founding president (2015–2017).

Vera was born in Barcelona on 25 September 1951, the seventh of nine children. As a Latvian-Russian-German descendant, she graduated from high school from the *Deutsche Schule* of Barcelona in 1970. She attended the University of Barcelona, enrolling in the Mathematics Department, not in the Biology Department as she had originally planned, because there was no waiting queue to enroll in Mathematics. She earned the equivalent of a master's degree in mathematics in 1982. After that, she decided to pursue graduate studies in Germany, where she received a PhD in natural sciences from the Free University of Berlin in 1986. Vera's partner is Juan José Egozcue and she is the mother of zoo, aquarium, and wildlife veterinarian Tania Monreal-Pawlowsky.

Biography

Professor Zhao Pengda was born in Qingyuan, Liao Ning Province in 1931. He graduated from the Geological Department of Beijing University in 1952, whereupon he was appointed as assistant to teach in the newly founded Beijing Geological Institute. In 1954, he was sent to Moscow, USSR as a postgraduate student, and studied methods of prospecting and exploration for mineral deposits under Professor A. A. Yakren at the Moscow Geological Surveys College obtaining his Ph.D. in 1958. The title of his dissertation was: “The geological characteristics and methods of exploration for stockwork type tin and tungsten ore deposits.” In 1960, he became Associate Professor at the Beijing Geological Institute, where he attained the rank of full professor in 1980. Meanwhile, the Institute was moved to Wuhan and named Wuhan College of Geology in 1975. Appointed its President in 1983, Professor Zhao retained this post following reorganization of the college in 1987 to create the China University of Geosciences (CUG). Later during his reign, CUG opened its second campus in Beijing.

Professor Zhao has been researching the use of mathematical and statistical methods in mineral exploration since 1956. In 1976, he began applying mathematical models to predict and assess mineral resources, specifically iron and copper deposits in a Mesozoic volcanic basin in southern China. This resulted in the book “Statistical Prediction for Mineral Deposits” (Zhao et al. 1983). In total, he has published three books and over 120 papers. His later research includes work on expert systems, statistical theory and methods of prediction, and integrated modeling of geochemical anomalies and ranking by favorability. He has taught courses in mathematical geology, statistical analysis of geoexploration data, and statistical prediction of mineral deposits.

In 1990, Professor Zhao organized and chaired the international workshop: “Statistical Prediction and Assessment for Mineral Deposits,” held in Wuhan and attended by 14 experts from outside China including Dr. Richard McCammon, then President of the International Association of Mathematical Geosciences (IAMG). As Father of Mathematical Geology in China, Professor Zhao has been a member of the IAMG for many years, furthering the field of mathematical geology through teaching and publications (e.g., Zhao 1992). In 1993 he was awarded the William Christian Krumbein Medal, which is the highest award the IAMG can bestow upon one of its members. In 1993, Professor Zhao also became Academician of the Chinese Academy where he chaired its geoscience section for many years. After his retirement as President of the China University of Geosciences he remains actively involved in research and supervision of Ph.D. students. In May 2020, CUG organized Professor Zhao’s 90th Birthday Celebration.

Plurigaussian Simulations

Nasser Madani

School of Mining and Geosciences, Nazarbayev University, Nur-Sultan city, Kazakhstan

Definition

Plurigaussian simulation is a stochastic technique for spatial modeling of categorical variables. An important characteristic of this technique is that the relationship and contact between categories can be identified by domain expert and imposed into the process of modeling.

Introduction

Categorical variables in geoscience-related fields usually are divided into two parts. The first part, nominal variables are the categories without any ordering. Some examples of this family are lithology, facies, rock types, alternations, permeable/impermeable, etc. The second part, ordinal variables are the categories with an intrinsic ordering or ranking. Several examples of this family are lithofacies sequence in sedimentary environment, class of mineral grades and geochemical anomalies (e.g., poor, medium, rich), intensity of minerals in a rock sample quantified on a quantitative scale (e.g., none, little, moderate, much, very much), clarity and color grades of particular minerals and stones, etc. Let’s denote the categorical variables as geo-domains throughout this text. Three-dimensional spatial modeling of these geo-domains can be implemented either by deterministic or stochastic approaches. In the former, the layout of the boundaries between two adjacent geo-domains can be specified based on the geological knowledge and one may obtain only one single scenario for positioning of this boundary. In the latter, however, a stochastic process determines the probable area of the boundaries among the geo-domains. In this context, several geostatistical simulation techniques are developed in the last decades. Among others, plurigaussian simulations are of paramount importance for modeling the geo-domains where some particular restrictions exist in contact boundaries. For instance, in modeling of a mineral deposit, from the

geological perspectives, it is possible that some of geo-domains never touch each other, meaning that there is no contact between them. This characteristic, known as forbidden contact can be modeled in resulting maps/scenarios by plurigaussian simulations.

History

Theoretical background of plurigaussian simulations was first introduced by Galli et al. (1994). In the past almost 26 years since the initiation of the first idea, many scholars used this technique for modeling the categorical variables in reservoir characterization, ore body modeling, rock fractures, and hydrogeology (Armstrong et al. 2011).

Essential Concepts

Plurigaussian simulations are natural extension of truncated Gaussian simulation. Matheron et al. (1987) first introduced the truncated Gaussian simulation for the purpose of simulating first the lithofacies in an oil reservoir and then to simulate the porosity and permeability within the built lithofacies. This methodology is developed for the cases when the geo-domains follow a sequential ordering. Plurigaussian simulation, however, is developed to model more complicated types of contacts that exist among the underlying geo-domains. For instance, Fig. 1 shows an example resulting map of truncated and plurigaussian simulations for modeling four geo-domains. Figure 1a shows that there is a sequence from geo-domain A to geo-domain D, which is obtained from the former method while Fig. 1b illustrates that the geo-domain A only touches geo-domain B and never is in contact with geo-domains C and D.

The rationale behind the truncation Gaussian and plurigaussian simulation is that the former considers one Gaussian random field (Fig. 1c), and the latter employs two or more Gaussian random fields (Fig. 1c and d) that are simulated entire area under consideration, and then a truncation rule (Fig. 1e and f) is used to turn these Gaussian values into geo-domains. Hence, the actual application of the plurigaussian simulations requires defining five main steps:

Step 1: Choosing the Truncation Rule

As shown in Fig. 1, the Gaussian random fields (Fig. 1c and d) need to be truncated in order to obtain the categorical maps (Fig. 1a and b). This needs definition of a truncation rule known as “flag,” where one can identify how the geo-domains are in content together. For instance, in Fig. 1e, the flag can represent the sequential contact between the geo-domains A to D and Fig. 1f depicts the flag that geo-domain A is

only in contact with geo-domain B and the latter is only in contact with geo-domains C and D. As a result, the configuration of the underlying flag that should be identified based on the geological interpretation of the domain identifies the permissible and forbidden contacts between geo-domains whether or not to comply with chronological ordering.

Step 2: Estimating the Truncation Thresholds

Splitting the Gaussian maps, given the preidentified flag, to obtain the categorical maps requires determining the corresponding thresholds. These numerical values can be obtained based on the proportion of each geo-domain. For N Gaussian random fields belonging to a vector random field $\mathbf{Z} = \{\mathbf{Z}(\mathbf{x}) : \mathbf{x} \in R^d\}$ with N components, and M geo-domains, $M - 1$ thresholds can be identified. Let's denote $g(\cdot)$ as the joint probability density function of the Gaussian random fields. For the purpose of computing the probability of presenting the i -th geo-domain at a particular sample location $\mathbf{x}$, one requires resolving the following formula:

$$P_i(\mathbf{x}) = \int_{D_i} g(z_1, \dots, z_N) dz_1 \dots dz_N \quad (1)$$

Where P_i is the proportion and D_i is the segment of the flag linked to the i th geo-domain (a subset of R^N defined by the thresholds). This formula may be resolved numerically or by trial and error.

Step 3: Inferring the Variogram of the Gaussian Random Fields

Variogram inference of the underlying Gaussian random field (s) is a key factor in plurigaussian simulation. Based on the mathematical relationship between the indicator variograms and the variograms of the Gaussian random field(s), one may infer a proper theoretical model for the variogram of interest by deriving its properties. The experimental indicator variogram can be computed experimentally through the recorded geo-domains at sample locations. For any separation vector h , the indicator cross variogram between two geo-domains (with indices i and j) is deduced by related non-centered covariance (Armstrong et al. 2011):

$$\gamma_{ij}(\mathbf{h}) = C_{ij}(\mathbf{0}) - \frac{1}{2} [C_{ij}(\mathbf{h}) + C_{ij}(-\mathbf{h})] \quad (2)$$

$$C_{ij}(h) = \text{prob}\{G(x) \in D_i, G(x+h) \in D_j\} \quad (3)$$

If D_i and D_j are rectangular parallelepipeds of R^N and the components of the vector random field G are independent, then the second member of Eq. (3) is a function of the direct covariances or variograms of the components of G and can be computed by utilizing Hermite polynomials (Emery 2007).

Plurigaussian Simulations, Fig. 1 Schematic representation of truncated and plurigaussian simulation techniques

Step 4: Generating Gaussian Random Fields at Sampling Points

Once the variogram of Gaussian random fields and the corresponding threshold(s) are obtained, the categorical variable at sampling points should be converted to the Gaussian values. This step generates the Gaussian values that first respects the variogram fitted in step 3 and also falls in the proper intervals imposed by flag and the truncation thresholds. For this purpose, a method called Gibbs sampler (Casella and George 1992) is used to generate such Gaussian values. The common procedure is as follows:

Initialization

In each sample point u_α , simulate a vector with N components u_α in $D_{i(\alpha)}$, where $i(\alpha)$ is the index of the geo-domain given at u_α .

Iteration

- (I) Select a data location u_α , regularly or randomly.
- (II) Compute the distribution of $G(u_\alpha)$ conditional to the other data $\{G(u_\alpha) : \beta \neq \alpha\}$. In the stationary case, this is a Gaussian distribution, with mean equal to the simple kriging estimation of $G(u_\alpha)$ and covariance matrix equals to the covariance matrix of the simple kriging errors.
- (III) Simulate a vector Z_α according to the previous conditional distribution.
- (IV) If Z_α is in compliant to the geo-domain dominating at u_α ($Z_\alpha \in D_{i(\alpha)}$), substitute the existing value of $G(u_\alpha)$ by Z_α .
- (V) Go back to a) and loop many times.

The Gibbs sampler presented is reversible, aperiodic, and irreducible. In a nutshell, the distribution of simulated values through the sample points converges to the conditional distribution of the target Gaussian random fields if the number of iterations increases significantly.

Step 5: Simulating Values at Target Grid Nodes

In this step, the simulation should be implemented to simulate the Gaussian random fields at the grid nodes, conditionally to the values acquired in the Step 4 and the same variogram model inferred in Step 3. For this, any algorithm can be applied for simulation of the Gaussian random fields: Cholesky decomposition, sequential Gaussian simulation, discrete spectral simulation, continuous spectral simulation, and turning bands (Chilès and Delfiner 2012, and references therein). Then, the simulated Gaussian values at target grid nodes should be converted back into the geo-domains using the preidentified flag.

Applications in More Detail

To illustrate the applicability of the plurigaussian simulations in a practical example, a small case study is presented in this section. This exemplar is inspired from a siliciclastic platform, for which it is composed of Sand, Shale Sand (ShSand), Shale (Sh), Limestone (Lst), and argillite limestone (argLst). For this case study, 100 sample points are irregularly available in an area and each facies is quantified at each sample point (Fig. 2). Based on the geological interpretation, Sand is in touch with ShSand and ShSand itself is in contact with Sh, whereas Sh is in contact with both Lst and argLst. This gradual change of facies from Sand to Lst and argLst is compatible with the sedimentology of the geological setting for this platform. All these knowledge contribute to identifying a flag as identified in Fig. 2. The variogram model of Gaussian random fields is obtained through an iteration over experimental variogram of indicators. Therefore, one cubic variogram with range of 100 m is inferred for both Gaussian random fields. The simulation results (two scenarios) are also shown in this figure. In total, 100 scenarios are generated and the probability map of each facies is calculated. These maps are applicable for quantification of uncertainty. In the end, one can obtain the most probable map as illustrated.

Current Investigations

There are several investigations of plurigaussian simulations, however, in this section; we only highlight some important developments of this simulation algorithm. Standard method of plurigaussian simulation (Emery 2007) generally is restricted to model few geo-domains and the Gaussian

random fields. Madani and Emery (2017) provided a generalization of the conventional plurigaussian simulation that allows the number of Gaussian random fields to be increased, appropriate for the chronological ordering of geological settings in such a way that younger geo-domains cross-cut the older ones. In such a case, all the geo-domains must be in contact altogether where modeling forbidden contact is not feasible. Maleki et al. (2016) introduced another exercise of this method, for which the geo-domains are, in the same manner, ordered hierarchically, but the forbidden contacts can also be dictated into the process of modeling. All these techniques are on the basis of stationary phenomena or homogeneous variability. Nevertheless, in the case of heterogeneous characteristics of geo-domains, one needs to renovate the stationary assumptions (Madani and Emery 2017) or utilize secondary information in replicating the possible trend for the corresponding geo-domains entire the region. For instance, an accessible information may be the seismic data. Another generalization of plurigaussian simulation is related to modeling the cyclic and rhythmic facies architectures (Le Blévec et al. 2018). The developed plurigaussian model takes into account the dampened hole-effect variogram model to delineate the rhythmicity in the vertical direction and a different stationary variogram model in horizontal plane. Plurigaussian simulations can also be integrated with multi-Gaussian simulation for establishing a modeling technique between geo-domains and continuous variables. Emery and Silva (2009) developed a joint simulation algorithm, where one categorical variable and one continuous variable can be modeled altogether given that the variability of the latter across the boundary of former is soft and there is a good association between these two variables. In this case, it is possible to consider several permissible and forbidden contacts among the geo-domains.

Controversies and Gaps in Current Knowledge

Despite the rapid development of plurigaussian simulations in the last decades, there remain some avenues for further research for modeling the geo-domains by this technique.

Deterministic Evaluation of Truncation Threshold

One of the main concern in plurigaussian simulations is identification of truncation thresholds based on the available data at sampling points. There are some approaches to define the declustering proportions to make it representative; however, fitting variogram step, Gibbs sampler and final truncation maps highly depend on the predetermined truncation threshold. Therefore, misspecification of these values leads to producing a huge bias in the results. Incorporation of uncertainty for truncation threshold in the process of modeling needs investigation.

Plurigaussian Simulations, Fig. 2 Application of plurigaussian simulation for modeling the facies in a siliciclastic platform

Variogram Analysis

In the case of having complicated contact relationship between geo-domains, manual variogram fitting is cumbersome. This is more difficult when the aim is to use joint simulation for incorporation of continuous variable as proposed in Emery and Silva (2009). An automatic technique or

semiautomatic technique may facilitate this issue. Another issue is related to lack of data. Whenever some geo-domains are scarce, modeling the variogram and inference its corresponding Gaussian variogram is not trivial. More work is needed to solve the issue of variogram analysis in the presence of scarce data.

Heterogeneity Characteristics of Geo-Domains

Nonstationary representation of geo-domains in a geological complex motivates one using the proportion curves (Armstrong et al., 2011). A common exemplar comes up when the proportions of the geo-domain of interest change vertically and laterally. Spatially varying proportions may be connected with spatially varying thresholds. Taking the advantage of spatially varying geo-domain proportions is disputing for the variogram inference and the computation of spatially varying truncation thresholds itself. More research is required to solve the issue of nonstationary phenomena of geo-domains without considering the spatially varying proportion curves.

Convergence of Gibbs Sampler

In the case of simulating plenty of sample points, a moving neighborhood often is used for solving the kriging system, based on the screen-effect approximation. However, this means that the Markov Chain may no longer converge to the required distribution or does not converge at all. More investigation is required to solve the issue of computational resources for using unique neighborhood in Gibbs sampler instead of moving neighborhood in the case when the data are numerous.

Complex Geological Features

Plurigaussian simulations still are suboptimal for modeling some complex geological features such as connectivity constraints, long-range geological structures, and coniform shapes (e.g., intrusive bodies, metamorphic geological process, infiltration by gravity, or deposition).

Cosimulation

Plurigaussian simulations still are restricted to modeling of one categorical variable. However, this variable may contain only a few geo-domains. More investigation is required for establishing a cosimulation algorithm for modeling two or more categorical variables. For instance, sometimes, rock types and alteration show good association in a deposit. The idea of further research can use of a cosimulation algorithm to reproduce such an association. Concerning this, one possible solution can be multivariate categorical modeling with hierarchical truncated simulation (Silva and Deutsch 2019).

Joint Simulation

Using plurigaussian simulations for joint simulation as proposed by Emery and Silva (2009) is restricted to only one categorical variable and one continuous variable. More investigation is needed for developing an approach for joint simulation of more than one continuous variable, while the categories remain to either one or several variables. Another avenue of research is related to the hierarchical simulation

algorithm for identifying truncation rule while there exist one or more geo-domains in this joint technique.

Summary and Conclusion

Plurigaussian simulations are advanced techniques for modeling the geo-domains with complexity in contact relationship. Flexibility of identifying the truncation rule (flag) and incorporation of geological perspectives lead to producing more realistic results compared to other simulation techniques. In this regard, particularly, forbidden contacts can be imposed into the process of modeling in the resulting maps. For implementation of this algorithm, five main steps were discussed: (1) choosing the truncated rule (flag), (2) estimating the truncation threshold(s), (3) inferring the variogram of the underlying Gaussian random fields, (4) Generating Gaussian random fields at sampling points, (5) simulating values at target grid nodes. Plurigaussian simulations can be implemented in commercial software such as ISATIS and in Petrel through PGS plug-in that is available on Schlumberger's Ocean Store. An open access MATLAB code is also available in IAMG website (iamg.org) attached to the work of Emery (2007). Besides many interesting solutions for modeling the complex geological features in this technique, there still exist several opportunities for further improvement. Few of them were discussed accordingly.

Point process statistics

Definition

In the geosciences irregular, random point patterns are studied, in 3D and 2D space. The “points” usually stand for objects of the same type, reducing the information on the objects to their locations; often the points are midpoints or small objects of the same size as the data grid cell. Additional information can be attached by so-called “marks,” which can be real numbers (characterizing perhaps size or type) or geometrical objects (pores or geological bodies). The mathematical models of point patterns are called *point processes*.

Overview

In geoscientific applications, the points may be positions of volcanoes, small deposits of ore, sinkhole centers, trap sites of precious stone placer deposits, centers of pores or crystals, etc. The corresponding patterns occur on all scales, from microscopic to plate-tectonic scale. The goals of point pattern statistics are for a concrete pattern:

- Classification of its type (clustering or regular)
- Understanding interaction between the points
- Determination of range of correlation
- Detection of correlation to covariables
- Fitting a model that helps to understand the process that formed the pattern

Typical point patterns in the geosciences are clustered and cannot be considered as stationary, a standard assumption of point process statistics. “Stationarity” means that a given

pattern can be considered as a part of a large pattern with similar random fluctuations everywhere in space. However, if one only aims consideration of short-range properties, clever choice of the window of observation gives sense to application of stationary methods, which is justified by Georges Matheron’s idea of “local ergodicity.”

Standard references to point processes and their statistics are Baddeley, Rubak and Turner (2016), and Illian et al. (2008). All formulas mentioned in this article can be found in these books. For statistical analyses of point patterns, the statistical R package *spatstat* is recommended. In the present short text, the theory for spatio-temporal point patterns is not given, as it is applicable to the concrete example considered, where the points are centers of sinkholes (see Fig. 1).

Point Process Theory

General

Many geometrical structures in the geosciences can be described by point patterns, where randomly distributed objects are described by points. This is done in the two- and three-dimensional case, while the present text considers mainly the 2D case. Sometimes the objects are additionally characterized by marks (e.g., numbers or vectors), which leads to marked point patterns. If the marks are bodies, one speaks of germ-grain processes or object-models. Clearly, a point pattern is not a regionalized variable or random field as studied in classical geostatistics, since it is given only in the isolated points that constitute it; also with real-valued marks,

Point Pattern Statistics, Fig. 1 Point pattern of 134 sinkhole centers in the region of the city Tampa. This sinkhole pattern from January 2020 in a rectangle of 19.0 km × 11.5 km in the region of the city of Tampa is a small subpattern of the large and spatially inhomogeneous pattern of all sinkholes in Florida, located at the South-West edge of a large cluster of sinkholes. It was selected as a nearly homogeneous pattern, with the aim to study possible short-range interaction of sinkholes in a relatively homogeneous geological situation with reduced influence of covariables such as population density (and thus of observation intensity). (Source: Florida Geological Survey publications, http://fddeploc.dep.state.fl.us/geodb_query/PubIndexQuery.asp)

it is not a regionalized variable. However, it is possible to transform a point pattern to such a variable by smoothing, see below.

The corresponding stochastic models are called *point processes* and *marked point processes*. It is always assumed that the structures are locally finite, that the number of points in bounded sets is finite. The corresponding mathematical theory is presented in Chiu et al. (2013) and Illian et al. (2008). It studies the probability laws of point processes, the interactions of points, and the description by statistical summary characteristics and many point process models. The present text concentrates on the facts necessary for first statistical steps.

Statistical methods for stationary point processes can be applied for the investigation of short-range interaction of the points, for the study of relationships at distances in the order of first neighbor distances. For this purpose, the window of observation W of observation is adapted to the point pattern so that it looks homogeneously distributed within W . For example, it may make sense to consider points in the interior of a single cluster, while the analysis of a total single cluster with much empty space around is questionable, see Illian et al. (2008, p. 264 and 268).

Intensity Function and Intensity

As the first step of a statistical analysis of a point pattern its *intensity function*, the spatially variable point density, $\lambda(x)$, should be determined, where x is a deterministic point that varies in the window of observation W . Mathematically $\lambda(x)$ yields the mean of the number of points $N(A)$ in a set A by integration,

$$E(N(A)) = \int_A \lambda(x) dx. \quad (1)$$

The intensity function can be estimated by smoothing (see below). Figure 2 shows the estimated intensity for the sinkhole pattern, with a simple parametric form.

In geological applications also relations to covariables help in the description of point density, for example, the distance to faults or relations to curvature or strain, see Eq. (7).

In the stationary case, $\lambda(x)$ is constant, called *intensity* and denoted by λ . Equation (1) simplifies to

$$E(N(A)) = \lambda \cdot v(A), \quad (2)$$

where $v(A)$ denotes the area of A . Clearly, λ is estimated statistically by

$$\hat{\lambda} = N(A)/v(A). \quad (3)$$

Point Pattern Statistics, Fig. 2 Empirical intensity function of the sinkhole pattern. According to the positions of the sinkholes at the South-West edge of a large cluster of sinkholes, the isolines of $\lambda(x)$ were chosen as lines in SE-NW direction, that is, $\lambda(x)$ is estimated in a parametrized way, not by smoothing. The intensity is measured in number per km^2 .

Pair Correlation Function and Further Summary Characteristics

The variability of point patterns is characterized by various summary characteristics. In general, the most powerful is the *pair correlation function* $g(r)$. It plays the role of Ripley's *K-function* $K(r)$ in the older literature and may be seen as an analogue of the variogram of geostatistics.

A short explanation is as follows. The term $\lambda K(r)$ can be interpreted as the mean number of points in a disc of radius r centered at a typical point of the pattern, not counting the disc center. Then the pair correlation function is given by

$$g(r) = \frac{dK(r)}{dr} / (2\pi r) \text{ for } r \geq 0. \quad (4)$$

Note that the intensity λ is eliminated. In the context of $g(r)$, the variable r should be interpreted as inter-point distance. Always $g(r)$ is nonnegative. If the point distribution is completely random, then

$$g(r) \equiv 1. \quad (5)$$

For large r the function $g(r)$ always takes on the value 1. If there is a finite distance r_{corr} with

$$g(r) = 1 \text{ for } r \geq r_{\text{corr}}$$

then r_{corr} is called *range of correlation*. This means that there are no correlations between point positions at distances larger than r_{corr} . And if there is a minimum inter-point distance r_0 , sometimes called *hard-core distance*, then

$$g(r) = 0 \text{ for } r \leq r_0.$$

The estimation of the pair correlation function is described in Baddeley et al. (2016) and Illian et al. (2008). Corresponding to the nature of $g(r)$ estimators of λ are used

for normalization. It should be determined only for large point patterns of (say) more than 100 points. The interpretation of empirical pair correlation functions is an art, which needs experience (Illian et al. 2008).

If the pattern analyzed deviates from the behavior expected for a sample of a stationary point process, the estimated $g(r)$ can for large r significantly deviate from the theoretical value 1. In such cases, the estimation may be improved by using ideas of the statistics for *second-order intensity-reweighted stationary* point processes. Then the estimators of intensity λ are replaced by estimators of the intensity function $\lambda(x)$ (Baddeley et al. 2016).

Figure 3 shows the empirical pair correlation function $g(r)$ for the sinkhole pattern of Fig. 1 obtained by the stationary and nonstationary approach. The curves have the typical form of pair correlation functions for cluster point processes. They suggest a cluster diameter between 0.2 and 0.5 km. There are

Point Pattern Statistics, Fig. 3 Empirical pair correlation functions. Empirical pair correlation functions for the pattern of sinkhole centers in Fig. 1, estimate ignoring nonstationarity (—) and estimate with intensity-reweighting (---) in comparison to the value of 1 for the CSR case (...). It is typical that the curve for the stationary approach is above that for the nonstationary approach. See the text for more information

nine point pairs of an inter-point distance smaller than 40 m. (This is very well related to a localized intense rain event.) The closest has a distance of 13 m, and the corresponding events happened in 6 days distance. Another pair of distance 40 m appeared in 2 days. Thus, there is strong clustering in space and time. The large values of $g(r)$ for small r indicate clustering also in this selected subpattern. The pattern may consist of many micro clusters, and these microclusters seem to be randomly distributed; they often are simply close point pairs. Any prediction based only on the pattern is difficult.

Point process statistics has many other summary characteristics, which may be considered as belonging to the class of multiple-point statistics. The most popular ones are:

- Distribution function $D(r)$ of the *distance to the nearest neighbor* from a typical point of the process
- *Spherical contact distribution function* $H_s(r)$, that is, distribution function of the distance from a random test point to the nearest point of the pattern

Many others can be found in Baddeley et al. (2016) and Illian et al. (2008). For the determination of directionalities in point patterns, for example, in the context of strain analysis, the Fry method is used (Rajala et al. 2018).

For the sinkhole pattern, Fig. 4 shows two summary characteristics, which aim to show gaps or regions of high point density:

- The 4-neighborhood graph, see Illian et al. (2008, p. 258)
- The Allard-Fraley estimate of regions of high point density, see Baddeley et al. (2016, p. 192).

Marked Point Processes

To each point x_n of a point process, a further datum m_n , called *mark*, can be added, such as a real number (perhaps tonnage

Point Pattern Statistics, Fig. 4 4-neighborhood graph and high-intensity regions. (left) Each sinkhole center is connected with its four nearest neighbors, which shows gaps in the point pattern. (right) High-intensity regions

of the ore deposit at x_n), a surface (perhaps a fault centered at x_n), or a three-dimensional object centered at x_n , see the article *Stochastic Geometry in the Geosciences*.

Stationarity of marked point processes means invariance of the distribution under translations which shift the points but retain the marks, that is, $[x, m] \rightarrow [x + \delta, m]$.

The intensity of a stationary marked point process is the intensity of the point process with the marks stripped off. The marks are characterized by the mark distribution, which in the case of real-valued marks is simply given by a distribution function. The corresponding mean is called the mean mark.

For the case of real-valued marks, stochastic models are available in the literature, for which formulas exist for model characteristics. Two simple cases are (a) independent marks and (b) marks that come from an independent random field $\{Z(x)\}$, that is, the mark of the point x_n is $Z(x_n)$. In the statistics of marked point processes summary characteristics called *mark-correlation functions* are of value, that is, functions that describe the spatial variability of the marks relative to the points.

An example for the application of these characteristics is Ketcham et al. (2005), which studies three-dimensional porphyroblastic textures. Figure 5 shows a volume rendering of a slice of the material obtained using computed tomography. For statistical analysis, such samples were converted to marked point patterns, where crystal centers = points and crystal volumes = marks.

Point process statistics for these data suggests distributional order or regularity at length scales less than the mean nearest-neighbor distance and clustering at great length scales. Crystals close together tend to be small, even after

accounting for the physical limitation that one crystal cannot nucleate within another. In another microstructure application, the points could be pore centers and the marks pore volumes.

Point Process Models

The Homogeneous Poisson Process, CSR

The theory of point processes has a standard “null model”: the *homogeneous Poisson process*. In its context statisticians often speak about *complete spatial randomness* (CSR). Between the points of a homogeneous Poisson process, there is no interaction, and it can be assumed that the points take their locations independently. The point numbers in disjoint sets are independent; this holds true not only for two sets but for any number of sets.

The homogeneous Poisson process is a stationary and isotropic point process. Its only parameter is the intensity λ . The name “Poisson process” comes from the fact that the number $N(A)$ of points in any set A has a Poisson distribution with mean $\mu = \lambda \cdot v(A)$, which means

$$P(N(A) = i) = \frac{\mu^i}{i!} \exp(-\mu) \text{ for } i = 0, 1, \dots \quad (6)$$

For the Poisson process, there exist many formulas for its distributional characteristics (Baddeley et al. 2016; Illian et al. 2008). In particular, the pair correlation function $g(r)$ has the simple form of Eq. (5).

When a statistician is able to prove by a test that a given point pattern can be seen as CSR, that is, as a sample of a homogeneous Poisson process, then any search for interaction between the points can stop, and any prediction is senseless. (That’s why the term “null model” is used.) Therefore, there are many tests of the CSR hypothesis, see Baddeley et al. (2016), Illian et al. (2008), and Myllymäki et al. (2017). Many of these consider an empirical summary characteristic for the pattern and analogous characteristics obtained by simulating CSR patterns, rejecting the CSR hypothesis if the empirical characteristic differs significantly from the simulated ones. For the pattern of sinkholes, the test using the pair correlation function leads to rejection of the CSR hypothesis. The values of $g(r)$ for r between 0.2 and 0.4 km are too large.

For the homogeneous Poisson process, the nearest neighbor distance distribution function $D(r)$ and the spherical contact distribution function $H_s(r)$ coincide and are equal to $1 - \exp(-\lambda r^2)$.

The Inhomogeneous Poisson Process and the Cox Process

The inhomogeneous Poisson process shares the most properties with the homogeneous one, only there is a spatially variable intensity function $\lambda(x)$. Care is necessary to

Point Pattern Statistics, Fig. 5 A porphyroblastic structure. Garnet crystals (red) and higher-density trace phases (such as zircon and iron oxides) (yellow) in a sample of garnet amphibolite schist. The width of the object shown is 25.5 mm and the thickness 3.1 mm. (Data courtesy of Richard Ketcham)

understand the main point: Of course, every point pattern has a randomly fluctuating point density, even a pattern for a stationary point process. However, in the case of the inhomogeneous Poisson process, the point density fluctuates in a predictable sense: If one could observe more than one sample, one would observe similar point densities in the same regions, for example, high point density along a geological fault; nevertheless the particular point locations may be fully random.

The point numbers in disjoint sets are independent and the number $N(A)$ of points in any set A has a Poisson distribution, the mean of which depends both on size and location of A . It is given by Eq. (1).

An example of application of an inhomogeneous Poisson process is the study of spatial correlation between gold deposits and geological faults in Baddeley (2018), where an intensity of the form

$$\lambda(x) = \exp(\alpha + \beta d(x)) \quad (7)$$

was used, where $d(x)$ is the nearest distance from x to a fault.

The inhomogeneous Poisson process can be made still more random: also the intensity function may be random. The resulting point processes are called *Cox processes* (after the English statistician David R. Cox) or “doubly stochastic Poisson processes” because of the two stochastic elements in the model. In this case, the intensity function is a random field: if this field is stationary then the Cox process is stationary too.

Of course, this field has to be positive, as an intensity function. Therefore, a Gaussian random field is not suitable in this context. A natural solution is to start from a Gaussian field $\{Z(x)\}$ and then to use the exponential $\lambda(x) = \exp(Z(x))$. This leads to so-called *log-Gaussian Cox processes*, which have been widely used in the modeling of environmental heterogeneity. Because of their construction, they can be seen as a link between point process statistics and geostatistics. They are simple enough to derive formulas for their statistical characteristics. For example, intensity and pair correlation function of a stationary and isotropic log-Gaussian Cox process are given by

$$\lambda = \exp\left(\mu_Z + \frac{1}{2}\sigma_Z^2\right) \quad (8)$$

and

$$g(r) = \exp(k_Z(r)) \text{ for } r \geq 0, \quad (9)$$

where μ_Z is the mean, σ_Z^2 the variance, and $k_Z(r)$ the covariance function of the Gaussian field $Z(x)$.

Cluster and Regular Point Processes

Some Cox processes are cluster point processes. Typical examples are Poisson cluster processes. These can be thought to be constructed starting from a homogeneous Poisson process. The points of this process, sometimes called “mother points,” are cluster centers (not points of the final process), and around each of these points “daughter points” are randomly scattered. The union of all daughter points is the cluster process. Formulas for its distributional characteristics can be found in Baddeley et al. (2016), and Illian et al. (2008).

Cluster point patterns appear frequently in the geosciences. A famous case are spatio-temporal patterns of epicenters of earthquakes, which are clustered in space and time (Ogata 2017). Of course, also the sinkhole pattern can be considered as a sample of a cluster process.

The pair correlation function of a cluster point process may have a pole at $r = 0$. The existence of a pole may indicate a fractal behavior of the structure related to the points (Agterberg 2014). However, poles can appear also in situations without any fractal structure, for example, when daughter points are scattered on segments, perhaps close to faults.

While the simulation of cluster processes is easy, their statistics present a challenge (Baddeley et al. 2016; Illian et al. 2008).

Another class of point processes are *regular point processes*, for example, “hard-core processes” with a positive minimum inter-point distance. Such a model would be used for the porphyroblastic structure in Fig. 5. “Gibbs processes” as mentioned below in the context of Markov Chain Monte Carlo are a popular class of such models.

Tools of Point Pattern Statistics

Smoothing

A regionalized variable is a quantity $Z(x)$ defined for every location x of space. Examples are porosity at x (either 0 or 1) or ore content at x (a nonnegative number, being the ore content of a sample (ball or cube) centered at x). The statistics of regionalized variables are statistics of random fields and sometimes this just goes under the name *geostatistics*. Point processes are not regionalized variables, but sometimes it makes sense to regionalize such structures, in order then to apply the strong methods of geostatistics. A natural approach is smoothing. For example, consider the number of points $Z(x)$ of a planar point process in the disc $b(x, R)$ divided by πR^2 for every point x of the space for some chosen radius R . For inhomogeneous point processes, this leads to estimates of the intensity function $\lambda(x)$. A problem is then the choice of the smoothing parameter R .

Simulation Techniques

Point processes are simulated in order to visualize the structure of some models, to generate samples for the investigation of statistical procedures, so-called test-patterns, or to demonstrate uncertainty. Here some important techniques are described, limited to the stationary case.

Simple Simulations

The simulation of many point processes models is a simple task. Here are two pseudocodes for the first steps, where *random* is a random number uniform on $[0, 1]$:

Simulation of a random point $x = (\xi, \eta)$ in a rectangle of side lengths a and b .

1. $\xi = \text{random} \cdot a$
2. $\eta = \text{random} \cdot b$
3. print $x = (\xi, \eta)$

Simulation of a sample of a homogeneous Poisson process of intensity λ in a rectangle.

1. generate a Poisson random number n of mean $\lambda \cdot a \cdot b$
2. for $i = 1$ to n generate random points x_i in the rectangle
3. print $(x_1, \dots, x_n)$

An elegant form of simulation of a Poisson random number is described in Illian et al. (2008, p. 71). In spatstat, a Poisson process pattern can be generated by the function `rpoispp`.

For more general models, care is necessary with the boundaries, for example, when simulating cluster processes: then mother points outside the window must not be ignored. Here the technique of so-called “exact simulation” can be used.

Markov Chain Monte Carlo

In particular, point processes with inhibition between the points, that is, with some degree of regularity, are simulated by the Markov chain Monte Carlo technique. A simple example is the simulation of the hard-core Gibbs process. It goes for a sample of n points in a window of simulation W as follows, if the hard-core or minimum distance between the points is R :

Place n points within W so that the distance between all point pairs is not smaller than R . Take randomly one of the points and give it a new position chosen randomly in the part of W where the hard-core condition is not violated. Continue this procedure many times, until the simulation process comes into a stationary state; in the beginning, there is some burn-in period. This method can be generalized both to the cases of a random number of points and forms of

interaction between the points more subtle than the simple hard interaction.

The sequence of point patterns in W after each step is a Markov chain in the state space of point patterns.

Reconstruction

Sometimes no model is available and one only needs patterns with similar statistical properties as a given empirical pattern, for example as training images. Then the method of reconstruction is recommended, a method in the spirit of multipoint statistics (Illian et al. 2008). Its first step is the determination of some statistical summary characteristics such as pair correlation function $g(r)$ plus(!) distribution function $D(r)$ or $H_s(r)$ for the original pattern. Then a new point pattern is constructed that has similar statistical summary characteristics. The construction starts with a CSR pattern of the same point number as the empirical pattern. Then one of its points is chosen randomly and replaced by a random point in W . If the new pattern has summary characteristics closer to the characteristics of the empirical pattern, the new point is accepted and a new trial is made. If not, a new point is chosen, etc. This iteration is repeated for many steps, where the determination of the summary characteristics of the whole pattern must be well organized. The minimization of the discrepancy may be improved by so-called simulated annealing. Also conditional simulation is possible, which means here simulation of a point pattern in some region given a subpoint pattern.

Summary

Point patterns make sense everywhere in geostatistics as representatives of locations of groups of objects irregularly distributed in space; marked point patterns stand for object systems. In statistical studies of microstructures, there are good chances to apply the powerful methods for stationary point processes. However, in larger scales big problems appear with instationarity and anisotropy. Here further research should change the situation, with adapted finite models and statistics.

Definition

Remote sensing systems represent nowadays an important source of information for the study of the Earth's surface. Due to their operation in all weather and all-time conditions, synthetic aperture radar (SAR) and polarimetric SAR (PoSAR) sensors are broadly applied in geoscience and remote sensing applications. Nevertheless, due to the coherent nature of the scattering mechanisms, SAR images are contaminated by the speckle noise. The speckle noise reduces the accuracy of post-processing as well as human

interpretation of the images. Hence, speckle filtering forms an important preprocessing task before the extraction of the useful information from SAR images.

Introduction

Adaptive filters and particularly the minimum mean square error (MMSE) filters have been extensively applied in PoLSAR to reduce speckle. Most MMSE-based PoLSAR filters have mainly concentrated on the collection of homogeneous pixels. In the refined Lee filter (Lee et al. 1999), the homogeneous pixels are chosen from eight edge aligned windows. In the Lee sigma filter (Lee et al. 2015), similar pixels are chosen from the sigma range. In Lee et al. (2006), the scattering model-based technique chose pixels of the same scattering media. In Wang et al. (2016), similar pixels are chosen using both intensity information and scattering mechanism. Based on a linear regression of means and variances of the filtered pixels, an infinite number of looks prediction (INLP) technique has been applied to improve the filtering performance of MMSE-based SAR image filtering (Yahia et al. 2020a). In Yahia et al. (2017, 2020b), an iterative MMMSE (IMMSE)-based filter is introduced. The IMMSE is initialized by a polarimetric filter ensuring a high speckle reduction level. Then, to improve the spatial detail preservation, the IMMSE filter is implemented for few iterations.

SAR Polarimetry

PoSAR data can be expressed using the scattering matrix S (Lee et al. 1999)

$$S = \begin{bmatrix} S_{hh} & S_{hv} \\ S_{vh} & S_{vv} \end{bmatrix} \quad (1)$$

The indices v and h represent the vertical and horizontal polarization, respectively. $S_{vh} = S_{hv}$ for reciprocal backscattering. PoSAR data can be expressed also in a vector form

$$\Omega = \begin{bmatrix} S_{hh} & \sqrt{2}S_{hv} & S_{vv} \end{bmatrix}^t \quad (2)$$

where “ t ” represents the transpose operator. The total power of a pixel i.e., $span$ is expressed as (Lee et al. 1999)

$$span = |S_{hh}|^2 + 2|S_{hv}|^2 + |S_{vv}|^2 \quad (3)$$

The covariance matrix C is expressed as (Lee et al. 1999)

$$C = E(\Omega \Omega^{*t}) \quad (4)$$

Polarimetric SAR Data Adaptive Filtering, Fig. 1 Span images: (a) original image, (b) Sigma filter, (c) INLP filter. A and B zones are used to compute ENL (22) and EPD (23), respectively

where “*” is the complex conjugation and $E(.)$ is the mathematical expectation.

Adaptive MMSE PolSAR Filtering

The PolSAR speckle filtering constraints are (Lee et al. 2015):

1. Conserve the polarimetric information.
2. Minimize the speckle noise in homogeneous zones (i.e., average all pixels $\hat{X}(i) = \overline{C}(i)$). Where $\hat{X}(i)$ represents the filtered covariance matrix.
3. Preserve the spatial details. The value of the original

covariance matrix should be maintained (i.e., $\hat{X}(i) = C(i)$).

SAR images are affected by the multiplicative (Lee et al. 1999)

$$y(i, j) = x(i, j) v(i, j), \quad (5)$$

v is the speckle noise with standard deviation σ_v and unit mean. x is the noise free pixel. For convenience, the (i, j) index is eliminated. The MMSE-based filtered pixel $\hat{x}$ is (Lee et al. 1999)

$$\hat{x} = \bar{y} + d(\text{var}(y))(y - \bar{y}) \quad (6)$$

where

$$b = \text{var}(x)/\text{var}(y), \quad (7) \quad b = x \quad (16)$$

Then

$$b = (\text{var}(y) - \bar{y}^2 \sigma_v^2) / (1 + \sigma_v^2) \text{var}(y) \quad (8)$$

$\bar{y}$ and $\text{var}(y)$ are computed adaptively using a local square window W .

In the refined (Lee et al. 1999) and sigma (Lee et al. 2015) filters, the MMSE estimate of the covariance matrix (i.e., $\hat{C}$) is

$$\hat{C} = \bar{C} + b(C - \bar{C}) \quad (9)$$

where b given in (8) is estimated from the span image (3).

Figure 1 displays the original and the filtered span images of Les-Landes PolSAR data, respectively. It can be observed that the sigma filter performed high spatial detail preservation level. However; the speckle reduction is low. The speckle reduction level could be increased by increasing the size of the window size but the spatial detail preservation will be decreased. To increase the performance of the MMSE-based filters, the MMSE formulation has been improved as follows

Infinite Number of Looks Prediction INLP Filter

By combining Eqs. (5) and (6) (Yahia et al. 2017).

$$\bar{\hat{x}} = \bar{y} + \frac{\text{var}(x)}{\text{var}(y)}(y - \bar{y}) = \bar{y} = x, \quad (10)$$

$$\begin{aligned} \text{var}(\hat{x}) &= E\left(\left(\bar{y} + \frac{\text{var}(x)}{\text{var}(y)}(y - \bar{y})\right) - \bar{y}\right)^2 \\ &= \left(\frac{\text{var}(x)}{\text{var}(y)}\right)^2 E(y - \bar{y})^2, \end{aligned} \quad (11)$$

$$\text{var}(\hat{x}) = \left(\frac{\text{var}(x)}{\text{var}(y)}\right) \text{var}(x) = d\text{var}(x), \quad (12)$$

then,

$$\hat{x} = x + \frac{(y - x)}{\text{var}(x)} \text{var}(\hat{x}). \quad (13)$$

Finally,

$$\hat{x} = a \text{var}(\hat{x}) + b, \quad (14)$$

where

$$a = (y - x)/\text{var}(x), \quad (15)$$

and

Equation (14) shows that the filtered pixel $\hat{x}$ is linearly related to its variance $\text{var}(\hat{x})$. This rule is applied to estimate the INLP filtered pixel (i.e., the parameter b) (Yahia et al. 2017).

The linear regression in (x, y) coordinates gives (Vaseghi 2000):

$$b = \bar{y} - a \bar{x}, \quad (17)$$

and

$$a = \sum_{i=1}^M (x_i y_i - M \bar{x} \bar{y}) / MV_x, \quad (18)$$

where V_x and $\bar{x}$ are the variance and the mean of the vector x , respectively. In (18), the parameters x_i and y_i represent the samples $\hat{x}_i$ and $\text{var}(\hat{x}_i)$, respectively. To conserve PolSAR information, it has been suggested that all the elements of the covariance matrices must be filtered equally as the multi-look process (Lee et al. 2015). However, it is observed in (18) that the filtered pixel b is not linearly dependent on y_i due to the square values of y_i . Hence, (17) can be written as:

$$b = \bar{y} \left(1 + \frac{\bar{x}^2}{V_x}\right) - \frac{\bar{x}}{MV_x} \sum_{i=1}^M x_i y_i = P \bar{y} + Q y', \quad (19)$$

where

$$P = \left(1 + (\bar{x}^2/V_x)\right) \quad (20)$$

and Q is a vector enclosing the samples

$$Q_i = (\bar{x}/MV_x) x_i. \quad (21)$$

To make b linearly dependent on y_i , the parameters P and Q must have the same values for all covariance matrix elements. Hence, the parameters P and Q were estimated from the *span* image and introduced in (19) to filter all the elements of the covariance matrix similarly. The real and imaginary coefficients of the off-diagonal elements of the covariance matrix were processed independently.

To assess the performance of the studied speckle filtering techniques quantitatively in terms of speckle reduction level, the equivalent number of looks is selected:

$$\text{ENL} = \hat{x}/\text{var}(\hat{x}) \quad (22)$$

To assess the ability of the filters in terms of spatial detail preservation, the Edge Preservation Degree (EPD) is

employed (Feng et al. 2011). The EPD in horizontal direction is:

$$EPD_H = \frac{\sum_{m,n} |\hat{x}(m,n)/\hat{x}(m,n+1)|}{\sum_{m,n} |y(m,n)/y(m,n+1)|}. \quad (23)$$

Table 1 shows the quantitative filtering results. The INLP filter ensured higher speckle reduction level (i.e., $ENL = 31 > 25$) and better spatial detail preservation ($EPD_{H-INLP} = 0.84126 > EPD_{H-sigma} = 0.8398$) than the 7×7 sigma. Figures 1b and c display the filtered sigma and INLP span images, respectively. Quantitative outcomes are verified visually where the INLP filter ensured better spatial detail preservation than sigma filter. The spatial resolution is significantly increased by the improved INLP filter. The spatial details in Figs. 1c are more contrasted than the one in Figs. 1b.

In addition to the ability of the adaptive MMSE filtering technique to reduce speckle, the conventional adaptive filters such as refined Lee, Lee sigma, are the most computationally efficient methods among other better speckle filtering techniques for huge datasets. In fact, the computational complexity of the PolSAR filter constitutes currently a great concern for practical implementations since for many of the new SAR systems such as TerraSAR-X, Cosmo-SkyMed, and Gaofen-3, the image sizes are huge (i.e., bigger than $10,000 \times 10,000$ pixels).

Unlike the scalar MMSE, in PolSAR MMSE-based filters, the span is used to estimate the weight b . However, it has been

demonstrated in Yahia et al. (2020c) that the span is a non-linear filter and the span statistics are function of the entropy H . Figure 2 displays the ENL of the span image. It can be observed that the statistics of the span change within different extended homogenous areas.

As result, for optimal application of the adaptive MMSE PolSAR filters, σ_v in (8) must be adapted to the statistics of the span image.

Summary and Conclusions

In this study, the adaptive MMSE PolSAR filtering is investigated. The sigma Lee PolSAR filter is particularly implemented. Results show that this filter was able to preserve spatial details with low ability to reduce speckle. To improve the adaptive MMSE filtering performance, the INLP filter is introduced. The filtered pixel was derived using a linear regression of means and variances of the filtered pixels. The linear regression rule has been adapted to PolSAR data in order to preserve the polarimetric information. Results show that the INLP outperformed sigma filter in terms of spatial detail preservation and speckle reduction.

Earth and Resource System Laboratory, Graduate School of Engineering, Kyoto University, Kyoto, Japan

Synonyms

Interstice; Void

Definition

A pore is a small open space or passageway existing between solid materials in a rock, also called a void or an interstice. Generally, pores primarily form at the same time as the formation of the host rock and/or are secondarily introduced by mechanical failures and/or chemical actions after rock formation. From their morphological features, pores can be classified into isolated pores and connected pores. Usually, the pore structure is described in terms of the geometrical features, including their shape, size, volume, connectivity, and tortuosity, of pore populations rather than an individual pore.

Introduction

Invariably, pores exist in the earth materials from soils in the shallow subsurface to rocks in the crust and at least in the upper mantle. In this chapter, pores and pore structures in rocks will be the focus and will hopefully benefit areas related to solid earth in geoscience and geoen지니어ing. Generally, pores in rocks are filled by groundwater at depths below the groundwater level. In rare cases, however, the pores are partially or fully filled by oil (petroleum) and/or natural gas or solid gas hydrate. More importantly, the connected pores play a function in the fluid flow path, which allows material circulations at local and global scales and affects Earth systems. In addition, pore fluid pressure, especially the over pore fluid pressure in seismogenic zones, possibly influences various phenomena in and around plate interfaces, such as great earthquakes and plate tectonics. Therefore, pore structure is one of the most fundamental and important characteristics of rocks in many areas of study, e.g., geology, geophysics, geochemistry, earth resources, and groundwater hydrology.

Pore structures in different rock types are dependent on their origin and their host rocks. Generally, pores in sedimentary rocks exist in the matrix and have a relatively small aspect ratio (the ratio of their length to width). Most pores in volcanic rocks usually exhibit spherical shapes because they

were formed from volcanic gas. On the other hand, pores in crystalline rocks, including plutonic rocks and metamorphic rocks, have larger aspect ratios, e.g., >100 , and are generally called fractures.

Visual Observation of Pore Structure

To reveal the pore structure, visual observation at various scales is the most fundamental approach and has been performed by various methods. In this section, a very popular sedimentary rock called Berea sandstone was used as an example to show several typical images of a pore structure of a rock. This Paleozoic sandstone quarried for more than 200 years in Ohio, USA, has been used widely as a building material and grindstone (Hannibal 2020). Moreover, Berea sandstone with homogeneous fabric and fine-to-medium grain sizes has been used as a rock testing material for laboratory hydrological and mechanical experiments and for the visual observation of pore structures worldwide.

Figure 1a is an image taken by an iPhone (Model: SE) camera, showing that any pore(s) is hard to identify, although mineral grains are visible. Therefore, it may indicate that the pore structure is hard to see with the human naked eye. Several holes (the pores) can be seen from images taken by a stereomicroscope, but the pore structure cannot be clearly identified, probably due to low contrast and the presence of many semitransparent minerals, such as quartz (Fig. 1b). Figure 1c is a polarized optical microscopic photo (open nicol) of a thin section of $\sim 30\ \mu\text{m}$ in thickness. The thin section was made up after fluidic resin dyed blue was impregnated in pores and then fixed thermally (Chen et al. 2018). Therefore, mineral grains and pores with blue color can be easily identified, and the pore structure is clearly visible. From this two-dimensional image, the pores can be considered to connect with each other in the three-dimensional domain, i.e., a well-connected pore network through Berea sandstone exists.

Figure 1d and e shows the images of X-ray CT (computed tomography) at different scales. Since the 1990s, medical X-ray CT with an $\sim 200\text{-}\mu\text{m}$ resolution has been utilized for rock core samples in the geosciences (Cnudde and Boone 2013). The important advantages of X-ray CT are as follows: (i) the internal structure in a rock sample can be imaged without cutting, i.e., nondestructive observation; (ii) the three-dimensional structure can be reconstructed; and (iii) its images are composed of digital data and suitable for numeral simulation and mathematical geosciences. Following the application of medical X-ray CT, micro-CT (high-resolution CT) with a typical resolution of $\sim 10\ \mu\text{m}$ (Fig. 1d and e and recently nano-CT with submicrometer resolutions were developed and applied. From such X-ray CT images, three-dimensional pore network models can be built and then used

Pore Structure, Fig. 1 Images of Berea sandstone with ~20% porosity. (a) A normal optical photo taken by an iPhone (model: SE) camera. (b) An image of stereo microscope, arrows show presence of holes (the pores). (c) An image of thin section taken by a polarized optical microscope under open Nicol condition; the blue color shows pores in where blue resin was impregnated and fixed. (d) A X-ray CT image in a

resolution of ~22 $\mu\text{m}/\text{pixel}$ of a cylindrical sample; the dark gray-black color spots show the pores. (e) A X-ray CT image in a resolution of ~8 $\mu\text{m}/\text{pixel}$ of a rock tip (courtesy to Kazuya Ishitsuka). (f) A SEM image of the sandstone sample surface grinded by fine grit size sandpapers (average particle size <23 μm); WD denotes working distance is an operation parameter of SEM

to simulate permeability and other physical properties (e.g., Takahashi et al. 2016).

Figure 1f is a surface image of a Berea sandstone sample taken via scanning electron microscopy (SEM). This image shows a similar pore structure to the polarized optical microscopic image shown in Fig. 1c. These images (Fig. 1c and f) are clearer than the X-ray CT images (Fig. 1d and e); however, their disadvantage point is two-dimensional. All the images mentioned above were obtained under atmospheric pressure conditions. Generally, pore structure in rocks is dependent on ambient pressure because pressure may cause pores to reduce their volume or size (Takahashi et al. 2016; Lin et al. 2020).

Quantitative Evaluation of Pore Structure

The most important parameter to evaluate pore structure in rocks should be the porosity defined by the following equation:

$$\varphi = \frac{V_{\text{pore}}}{V_{\text{total}}} \quad (1)$$

where porosity φ is usually in %, V_{pore} is the cumulative pore volume in a rock sample, and V_{total} is the total volume including both solid materials and pores in the sample. Generally, only the connected pore volume in rock samples can be measured in most laboratory experiments. Thus, the measured porosity is also called effective porosity. Because only connected pores contribute to fluid flow and other transportation properties, “effective” porosity is more important than “true” porosity, including isolated pores. The other similar parameter is the void ratio, defined as the ratio of the cumulative pore volume in a rock sample and the cumulative solid volume of the sample. The void ratio can be determined uniquely from the porosity. Porosity is more popularly used in rock mechanics areas, but the void ratio is more popularly used in soil mechanics areas.

As direct measurement methods to determine the porosity of a rock sample, the cumulative pore volume (V_{pore}) in the sample and the total volume (V_{total}) of the sample must be measured, as shown in Eq. (1). Three main porosity measurement methods are utilized widely. As the first method, called the buoyancy method, derives V_{pore} from the difference between masses (or weights) of a rock sample under completely water-saturated and completely dried states and V_{total} from the difference between masses of the completely

water-saturated sample in air (atmosphere) and in water based on Archimedes' principle (Franklin 1979). The second method uses a helium gas pycnometer to measure the cumulative solid volume (V_{solid}) of a dry sample based on Boyle's law of the volume-pressure relationship (Blum 1997). In addition, the sum of this V_{solid} and the cumulative pore volume V_{pore} obtained by the difference of water-saturated and dried sample masses gives the total sample volume V_{total} . Therefore, porosity φ can be easily determined by $V_{\text{pore}}/V_{\text{total}}$. The third method called mercury intrusion porosimetry uses a porosimeter to determine not only the total volume (both solid and pore volumes) of a dry rock sample but also the cumulative pore volume from the volume of mercury intruded into the pores under high pressures (ASTM D4404–18 2018).

In addition to the laboratory measurement methods of rock porosity mentioned above, several indirect measurement/estimation methods are frequently applied in geoscience and geoenvironmental areas. In particular, geophysical loggings are widely utilized in drilling and/or drilled boreholes because they have an important advantage in which a continuous depth distribution of porosity can be obtained. Nuclear logs, including neutron logs and density logs, are available; the former uses neutrons to measure the quantity of water (H_2O) in the completely water-saturated rocks around the borehole to determine porosity, and the latter uses gamma rays to measure the bulk density of rocks and then to derive porosity. In addition, porosity depth profiles can be estimated based on the correlations (empirical equations) between porosity and elastic wave velocity from sonic (acoustic) logs and electric resistivity from resistivity logs. The porosity of rocks typically changes from <1% for hard rocks to >50% for soft rocks. For example, the porosity of Berea sandstone shown in Fig. 1 is approximately 20% (Lin et al. 2011). Generally, the porosity decreases as the depth increases in sedimentary basins. As an example, porosity changed from ~60% at a depth of 100 m below seafloor (mbsf) to ~20% or less at 3000 mbsf in the Nankai Trough Subduction Zone drilling site C0002 (Kitajima et al. 2017).

Pore size distribution is another important characteristic of pore structure that may affect fluid flow properties through the pore network. Under the assumption of the same effective porosity, for example, the larger the pore size is, the more easily the fluid flows through the pore network. In principle, pore size distribution can be evaluated by analysis of images such as those shown in Fig. 1. A more widely used technique is the mercury intrusion porosimetry method, which can determine not only the cumulative pore volume but also the pore volume corresponding to a certain distribution of pore sizes (ASTM D4404–18 2018). In this method, the non-wetting liquid (mercury in this method) can be forced into the connected pores by applying external pressure. The size of the pores that are intruded is inversely proportional to the applied pressure; thus, the pore size can be estimated from the

Pore Structure, Fig. 2 Pore size distributions of a Berea sandstone sample by mercury intrusion porosimetry. For determination of the pore size distribution, a cylindrical model of pore shape was assumed (ASTM D4404–18 2018)

pressure based on the Washburn equation. Mercury intrusion porosimetry is useful only for measuring the pores connected to the outside of the rock sample. This method gives only the volume of intrudable pores that have an apparent diameter corresponding to a pressure within the pressurizing range of the testing instrument; however, it does not give the true sizes of individual pores. Figure 2 shows the pore size distribution of a Berea sandstone sample obtained by mercury intrusion porosimetry, similar to that presented by Lin et al. (2011).

Relationships Between Porosity and Other Physical Properties

As an internal factor of rocks, pore structure is not only related to the physical properties of the rocks but also affects the properties. In addition, the types of fluids existing in the pores, e.g., water, oil, air, and pore fluid pressure in the pores, may also affect the physical properties of the rocks. The bulk densities of a rock in both the water-saturated and dried states are inversely proportional to porosity. Elastic wave velocities (P- and S-wave velocities), electric resistivity (the inverse of electric conductivity), strengths (e.g., compressive and tensile strengths), and Young's modulus increase as porosity decreases. Permeability shows a positive correlation with porosity but is also dependent on the pore size distribution. The thermal conductivity of rocks shows a negative correlation with porosity because solid minerals have higher thermal conductivity than fluids in the pores (Lin et al. 2020).

Summary

Pores must be available in all rocks occurring in the Earth's crust down to depths of several tens of kilometers

underground. Knowledge of pores and pore structure is important for geosciences and geoengineering. In this chapter, the definition, visual observations, quantitative evaluations, and relationships with the other physical properties are briefly described. Only fundamental knowledge is shown above and may not be sufficient for many readers. Fortunately, abundant previous research articles on the pore structure of rocks have been published in various scientific journals.

³Imperial College, London, UK

Definition

Porosity is a fundamental property of material in general and geomaterials (soils and rocks) in particular, being used in many fields such as material science, earth science, hydrogeology, rock and soil mechanics, geotechnical and environmental engineering, petroleum geoscience and engineering etc. Porosity ($\emptyset$) is a measure of the void space in soils, rocks and it is defined as the ratio between the pore volume (V_p) and the total volume (V_t) or the bulk volume (V_b). A conceptual model of geomaterial (soils, rocks), also known as a petrophysical model, is shown in Fig. 1a, consisting of three major components, i.e., solid, pore space and pore-filling fluids. Porosity can be in fraction (see Eq. 1a) or in percentage (see Eq. 1b). An example of how to calculate the porosity of an idealized granular medium made of uniform spherical grains arranged in a cubic packing is shown in Fig. 1b.

Fundamental Types of Geomaterial Porosity (Soils, Rocks)

Porosity of idealized spherical grain packings as shown in Fig. 2 has been studied for a long time (e.g., Graton and Fraser 1935), for which one single concept of porosity is enough to characterize the pore space. In nature, however, there are many diverse rock types belonging to three main groups of rocks, i.e., *igneous, sedimentary and metamorphic*. Igneous rocks form due to colling and solidification of a magma rising from the deeper part of Earth's crust or mantle. Sedimentary rocks are formed by deposition and cementation of sediment particles or by precipitation of minerals from water. Metamorphic rocks are formed by changes of preexisting rocks under the extreme conditions of heat, pressure, or reactive fluids. Consequently, the porosity concept has to diversify to characterize better the rocks in the real geological conditions. Before presenting some geological and engineering

Porosity, Fig. 1 Porosity of a conceptual geomaterial

classifications of porosity in the next section three fundamental types of porosity are explained below:

Total Porosity

As defined in Eq. 1a, b it is the ratio of the total pore space to the total volume of rocks.

Effective Porosity

Is the ratio of interconnected pore volume with respect to the total volume of rocks, being less than the total porosity in most cases. The isolated pores, partially filled pores or micropores that cannot transmit the fluid are not considered in the effective porosity.

Critical Porosity

Raymer et al. (1980) published some empirical velocity–porosity relations based on observations of the velocity change in a transition from solid to suspension, leading to the creation of the critical porosity concept. Initially conceptualized for a relatively simple clean sand, it has expanded to more complex rocks, i.e., rocks have a characteristic porosity above that they behave as a suspension, and this boundary value separates their mechanical and acoustic behavior into two distinct domains (Nur et al. 1998). The critical porosity plays an important role in rock physical modeling and construction of rock physical template for seismo-petrophysical characterization of complex hydrocarbon reservoirs (Giao et al. 2021).

The idealized packings in Fig. 2 represent the most simplified cases of clean sand or sandstone with single-porosity system (i.e., interparticle pores). Fig. 3a shows a well-sorted grain packing whose void space is reduced with time due to precipitation, cementation and infilling of the pore spaces as shown in Fig. 3b. Due fracturing a double porosity systems is developed (Fig. 3c). Some other major rock types like

carbonate rocks that account for approximately 50% of oil and gas production around the world or fractured igneous and metamorphic rocks can have multiple-porosity systems, combining primary and secondary porosities of both matrix and fractures (Fig. 3d). A possible difference between the double porosity systems in Fig. 3c and d is that in the latter case the primary porosity of matrix might be very small, e.g. cases of carbonates, igneous rocks. When the matrix porosity is insignificant the geomaterial is considered a fractured medium. Types and distribution of pores within the rock mass exert strong control on petrophysical characteristics of these rocks.

There are a number of mathematical models of porosity change with time and depth. For example, a one-dimensional compaction model can be described in its simplest form by a nonlinear diffusion equation as follows

$$\frac{\partial \phi}{\partial t} = \lambda \frac{\partial}{\partial z} \left\{ k(1 - \phi) \left[- \frac{\partial \sigma'}{\partial z} (1 - \phi) \right] \right\} \quad (2)$$

Where: t is time; z is depth; ϕ is the normalized porosity at depth z ; λ is the ratio of the hydraulic conductivity to the sedimentation rate; σ' is the effective overburden/stress; ϕ is the normalized porosity at depth z . Eq. 3 can be used to simulate time-dependent compaction of rocks in a sedimentary basin, which occurs when accumulating sediments compact under their own weight, expelling pore water in the process. A good analytical solution of Eq. 3 can be found in Fowler and Yang (1998).

Classification of Porosity

While in geotechnical engineering classification of porosity is not much paid attention to, in petroleum geoscience and

Porosity, Fig. 2 Porosity of various idealized spherical grain packings

Packing	Basal layer	3D view	Top view	The second layer
Cubic: ($\Phi = 47.6\%$)	square packs			same as the underlying layer
Hexagonal ($\Phi = 39.5\%$)				shifted laterally with half a radius in one direction on the underlying layer
Rhombohedral ($\Phi = 26.0\%$)				shifted diagonally, dropped into the square centers of the underlying layer
Orthorhombic ($\Phi = 39.5\%$)	rhombic packs			same as the underlying layer
Tetragonal ($\Phi = 30.2\%$)				shifted laterally with half a radius in one direction on the underlying layer
Triclinic ($\Phi = 26.0\%$)				shifted diagonally, dropped into the square centers of the underlying layer

Porosity, Fig. 3 Types and changes of porosity

			
(a) High (primary) porosity	(b) Low (primary) porosity	(c) Fracture (secondary) porosity	(d) Total (combined) matrix and fracture porosity

engineering the classification of porosity is extensively used for hydrocarbon potential assessment, reservoir characterization, reserve estimation etc. There are two widely used classifications of porosity in these fields, i.e., geological classification and engineering classification (Tiab and Donaldson 2015).

Geological Classification of Porosity

The *primary porosity* was formed during deposition of clastic sedimentary rocks (Fig. 3a and b) or during the cooling and solidification process of igneous rocks, while the *secondary porosity* (Fig. 3c and d) is caused by the changes after formation of rocks.

Primary porosity consists of the following void types: (i) *Intercrystalline voids* between cleavage planes of crystals,

between individual crystals, and in crystal lattices. They are mostly of sub-capillary size (less than $2\ \mu\text{m}$ in diameter), and can be called microporosity; (ii) *Intergranular or interparticle voids* between grains, i.e., interstitial voids of all kinds in all types of rocks. These voids range from sub-capillary to super-capillary size (greater than $0.5\ \text{mm}$ in diameter); (iii) *Bedding voids* along the bedding planes caused by differences of sediments deposited, i.e., particle sizes and arrangements, the depositional environment; (iv) *Bio-induced voids* that are vuggy and irregular voids resulting from the accumulation of detrital fragments of fossils, packing of oolites, voids created by living organisms at the time of deposition.

Secondary porosity is the result of geological processes occurring after original formation or rocks such as post-

Porosity, Table 1 Classification of porosity and permeability for clastic reservoir characterization

Porosity (%)	Reservoir quality	Permeability (mD)	Reservoir quality
0–5	Negligible	<1	Poor/tight
5–10	Poor	1–10	Fair
10–15	Fair	10–50	Moderate
15–20	Good	50–250	Good
>20	Very good	>250	Very good

deposition diagenesis and catagenesis processes for clastic sediments, dolomitization of carbonates, solution, fracturing, faulting of carbonate, igneous and metamorphic rocks. Main types of secondary porosity are: (i) *solution porosity*; (ii) *dolomitization porosity*; (iii) *fracture porosity*;

Engineering Classification of Reservoir Porosity

An example of engineering classification of porosity used in hydrocarbon reservoir characterization is shown in Table 1 below. It is noted that the engineering criteria change with time, depending on reservoir type and technology advancement, say, more than 50 years ago a permeability of 50 mD indicated a tight reservoir (Tiab and Donaldson 2015) or while a 5%-porosity is negligible for a sandstone reservoir it is the maximum one can expect from a fractured granite basement reservoir.

Related Parameters

Void Ratio

In soil mechanics a variant of porosity named void ratio (e) is commonly used instead, defined as the ratio between the volume of voids and volume of matrix as defined below:

$$e = \frac{V_p}{V_m} = \frac{V_p}{V_t - V_p} = \frac{\emptyset}{1 - \emptyset} = \frac{n}{1 - n} \quad (3)$$

Where: e is void ratio; $\emptyset$ is porosity, similarly n is also porosity as commonly denoted in soil mechanics or geotechnical engineering; V_t , V_p , V_m are the same as in Eq. 1a, b (Fig. 1a).

Tortuosity

Tortuosity (τ) of a porous material is the ratio of actual flow path length (L_a) to the straight distance between the ends of the flow path (L) as defined in Eq. 4 and shown in Fig. 4 with a dye tracer dispersion. Tortuosity can be of different types, i.e., geometric, hydraulic, electrical, and diffusive. It is a useful parameter to study the structure of porous media, their electrical and hydraulic conductivity, the travel time and length for tracer dispersion (Ghanbarian et al. 2013):

$$\tau = \frac{L_a}{L} \quad (4)$$

**Porosity, Fig. 4** Definition of tortuosity

Permeability and Porosity-Permeability Relationship (Poro-perm)

Permeability (k) is defined as the ability of geomaterial (soils, rocks) to let the fluids flow through under a hydraulic/pressure gradient or loading. In 1856 Henry Darcy, a French engineer, based on laboratory experiments of water flow through core sand samples, developed an equation (Eq. 5) that had become a valuable mathematical tool to determine hydraulic conductivity for groundwater flow or permeability for hydrocarbon flow as follows:

$$V = \frac{q}{A_c} = \frac{k}{\mu} \frac{dp}{dl} \quad (5)$$

Where: v is the velocity of fluid flow (cm/s); q is the flow rate (cm³/s); k is the permeability of rocks in Darcy (D), 1D = 0.986923 μm²; A_c is the cross-section of the core sample (cm²); μ is the viscosity of the fluid in centipoises (cP); dp/dl is the pressure gradient in the direction of flow (atm/cm).

Porosity and permeability form a couple of most related petrophysical parameters, with the latter being more difficult to be tested and estimated comparing to the former. That is why one always tries to establish some empirical relationships between these two parameters based on the core measurements. One early and common method is to plot porosity (on a linear scale) against permeability (on a logarithmic scale) and observe a curve fitting trend called poro-perm, which can be

used to predict permeability based on porosity values. For a non-linear porosity-permeability relationship, considering the rock heterogeneity, Kozeny-Carman equation is a good mathematical model for permeability prediction as widely used in petroleum engineering (Tiab and Donaldson 2015), and namely:

$$k = \frac{1}{K_{ps} \tau S_{vgr}^2} \frac{\emptyset^3}{(1 - \emptyset)^2} \quad (6a)$$

$$k = \frac{1}{5S_{vgr}^2} \frac{\emptyset^3}{(1 - \emptyset)^2} \quad (6b)$$

Where: k is permeability (D); K_{ps} is the pore factor; τ is the tortuosity; S_{vgr} is The specific surface area per unit grain volume (cm⁻¹); $\emptyset$ is the effective porosity; The product ($K_{ps} \cdot \tau$) is often taken equal to a numeric value, say, 5 for many porous rocks as shown in Eq. 6b, but it can vary from 2 to 5 and up depending on case by case.

Methods to Determine Porosity

Porosity can be directly measured on the soil and rock samples in the laboratory by various methods such as buoyancy, helium porosimeter, fluid saturation, mercury porosimetry (Glover 2020; Ulusay 2015), thin section analysis, digital rock physics analysis or indirectly determined by analysis of well log curves, e.g., density, sonic, neutron, resistivity, NMR logs (Tiab and Donaldson 2015). In geotechnical engineering, the porosity and void ratio of fine-grained soils like clays are commonly determined using the popular one-dimensional consolidation or oedometer test (ASTM D2345 2020).

Summary or Conclusions

Porosity is a fundamental property of soils and rocks, having many important applications in earth science, hydrogeology, geotechnical engineering, environmental engineering, petroleum geoscience and engineering etc. Extensive studies have been done on porosity since very early time of science and engineering development. Porosity of some clean sands can be calculated based on idealized spherical packings, but with time porosity is reduced due to geological process occurring after the rock formation such as cementation, solution, infilling of the pores, fracturing. Consequently, for rock characterization the porosity concept has to diversify and some classifications were proposed, e.g., geological and engineering classifications. There are two approaches to determine porosity directly and indirectly. The former is conducted on the core samples in the laboratory using various techniques,

while the latter is predominant in the oil and gas industry based on analysis of well log data.

Porous Medium

Jennifer McKinley
Geography, School of Natural and Built Environment,
Queen's University, Belfast, UK

Definition

A porous medium can be defined as a material that contains spaces, which, when continuous in some way, enable the movement of fluids, air, and materials of different chemical and physical properties. The ability of a porous medium to permit the movement of fluids, air, or a mixture of different fluids is related to porosity and the variability of pore

characteristics in that the presence of interconnected pore spaces, and thus permeability properties of the material, enables the movement of fluids and accompanying materials.

Characteristics of Porous Medium

The characteristics of a porous medium are a result of variability in porosity and permeability, and the spatial continuity of these properties (McKinley and Warke 2006). Porosity as defined by Tucker (1991) is a measure of the amount of pore space in a porous medium and can be characterized as total or absolute porosity and effective porosity. Total or absolute porosity refers to the total void space within a porous medium including void space within grains. Effective porosity can be described as the interconnected pore volume in a porous medium (McKinley and Warke 2006). Effective porosity is more closely related to permeability, which can be defined as the ability of a porous medium to transmit fluids. Permeability is related to the shape and size of pores or voids and pore connections throats), and also on the properties of the fluids involved (i.e., capillary forces, viscosity, and pressure gradient). Permeability as calculated from Darcy's law, in simple terms, is a measure of how easily a fluid of a certain viscosity flows through a porous medium under a pressure gradient (Allen et al. 1988).

Depositional and Diagenetic Characteristics of Geological Porous Media

Geological materials exhibit inherited characteristics from their depositional, compaction, and cementation or crystallization history (McKinley and Warke 2006). This results in individual pores or voids which vary in size, shape, and arrangement, directing the movement of fluids, air, and accompanying materials along preferred pathways and at differential rates. Natural porous medium such as rocks seldom retain their original porosity (McKinley and Warke 2006). The key factors that control porosity and permeability in geological porous medium are primary depositional characteristics (including fabric features) and diagenetic features such as cements and salts (Worden 1998). Primary depositional processes produce fabric characteristics, which in turn may be further modified by processes such as compaction and cementation. This results in primary and secondary porosity. Primary porosity is developed as a sediment is deposited and includes inter- and intraparticle/granular porosity (Tucker 1991). Secondary porosity of a porous medium develops during diagenesis by dissolution or removal of soluble material and through tectonic movements producing fracturing. Fractures or vugs within geological materials may contribute

substantially to the flow capacity (i.e., permeability properties) but contribute little to absolute porosity of a porous medium. Secondary diagenetic precipitation, in the form of cements and salts, has the potential to seal fractures or vugs and reduce the permeability properties of a porous medium. The predominant cements, which affect sandstone porous media, comprise carbonates, clay minerals, and quartz cements. Aspects of carbonate, quartz and clay cementation in sandstones have been comprehensively covered in three special publications (Morad 1998; Worden and Morad 2000, 2001). The variability of porosity in limestone porous media tends to be more erratic in type and distribution than for sandstones (Tucker 1991). Based on the seminal classification scheme by Choquette and Pray 1970, porosity types in carbonate porous media can be defined as fabric selective, depending on whether pores are defined by the fabric (grains and matrix) of the limestone (e.g., intercrystalline), and non-fabric selective, porosity that cuts across the actual rock fabric (e.g., fracture porosity). Stylolites in carbonate porous media can form a type of porosity in terms of acting as conduits for fluid movement or conversely stylolites can produce a reduction in porosity of the porous medium through the accumulation of clays and insoluble residue. Porosity in crystalline porous media, including igneous and metamorphic, occurs generally as a result of fracturing, granular decomposition or dissolution, and may be accentuated by mineral alignment or banding.

Heterogeneity of Porous Medium

No naturally occurring porous medium is homogeneous but some are relatively more homogeneous than others. The problem of nonuniformity or heterogeneity of a porous medium is inherent even at the pore scale, since individual pores vary in size, shape, and arrangement. Small-scale features such as pore geometry or laminae also affect the heterogeneity of porous medium.

By definition a reservoir porous medium, such as sandstone, must contain pores or voids to enable the storage of oil, gas, and water, which must be connected in some way to permit the movement of the same. Fluids of differing physical properties (oil, gas, and water) move through heterogeneous porous media via preferred pathways and at differential rates. Primarily this is due to the variability in porosity, permeability, poro-perm relationship, viscosity, tortuosity, interfacial tension (wettability), and spatial continuity of the porous medium. Knowledge of how the petrophysical properties of porosity and permeability vary throughout materials and identifying the processes responsible for their reduction is important in accurate reservoir modeling of porous media.

The challenge to studies of porous media description, and intrinsically of heterogeneity, can be summarized as to:

- Describe the geology with as much detail and as realistically as possible and in a quantitative approach.
- Assess the spatial distribution of heterogeneities including cements, salts, contaminants, etc., and their effect on fluid flow.
- Subdivide the porous medium into hydraulic or flow units (units that under a given driving force behave differently and in which the variation of properties is less than the hydraulic or flow units above and below).

In addition, studies must go beyond data capture to using this information in the development of mathematical simulation models that depict porous medium behavior accurately and effectively, all of which combines to give a greater understanding of fluid flow processes in a porous medium to optimize recovery and aquifer capabilities. The issues which arise in porous medium description are well documented. The recurrent themes are:

- The detail required to adequately quantify the lateral variability of physical properties far surpasses the detail of sampling (interpolation, extrapolation, and informed interpretation are necessary).
- Many heterogeneities have a spatial distribution much less than the average well or sample spacing.
- Heterogeneity at small scale is homogenized, simplified, or smoothed over within mathematical modeling.
- Averaging of heterogeneity data for modeling purposes can lead to underestimation of their effect on porosity and permeability.

Conclusions

A porous medium contains spaces or voids that, when connected in some way, permit the movement of fluids, air, and associated materials. Porous media tend to be heterogeneous within a larger ordered framework, as a function of scale. At the pore and microscale, the sorting and packing of grains can be markedly variable. Random variations or heterogeneous elements at the pore scale may be sufficiently small to be considered homogeneous at a larger scale, e.g., lamina, stratum, or bedding scale. Porous media, therefore, may appear to be both heterogeneous and homogeneous: depending on the scale of measurement being considered. In view of this it is essential that the scale of measurement being considered be clearly stated. The importance of depositional history in naturally occurring porous media and

diagenetic heterogeneities including the influence of cementation and the diagenetic growth of minerals on porous media need to be fully assessed and recognized in any modeling approach.

Power Spectral Density

Abhey Ram Bansal¹ and V. P. Dimri²

¹Gravity and Magnetic Group, CSIR- National Geophysical Research Institute, Hyderabad, India

²CSIR- National Geophysical Research Institute, Hyderabad, Telangana, India

Definition

The power spectral is used in many branches of earth sciences to carry out various mathematical operations on geophysical data to understand various earth processes and earth structure. The power spectral density is a representation of power of the signal in the frequency domain. The representation of data in the frequency domain found many applications.

Introduction

The geophysical measurements carried out in space/time represent the variations of physical measures in space/time. Exploration geophysics aims to find information about the subsurface distribution of physical properties from the surface/air/ship/satellite measurements. The distribution of physical properties in the subsurface is further interpreted to find the anomalous bodies containing hydrocarbons, minerals, water or to understand the crustal structure of the Earth. These measurements are often carried out at equal intervals along the roads (profile mode) or in a grid pattern (2-D survey), depending on the study's aim. The study of variation with space and time is carried out to understand the sub-crustal structure or seismic source nature.

The transformation from space/time to frequency domain is often useful since many mathematical operations in the frequency domain become easy to carry out and further useful to find the physical properties of the subsurface of the Earth. Space/time series can be decomposed in the sum/integral of the harmonic waves of different frequencies, known as Fourier analysis or Fourier transform (FT). To carry out the FT, the time/space series should be of limited length, periodic, or satisfying the condition of absolute integrability, which can be defined as: if $x(t)$ is a continuous function of space/time, then integration of the square of the time/space series is finite (Bath 1974):

$$\int_{-\infty}^{\infty} |x(t)|^2 dt < \infty \quad (1)$$

A continuous time/space series can be described in the FT:

$$X(k) = \int_{-\infty}^{\infty} x(t) e^{-jkt} dt \quad (2)$$

where k is wavenumber $= 2\pi f$ and f = frequency. The advantage of FT is that we can carry out some operations in the frequency domain, which can be further changed back to space/time series using the formula of inverse Fourier transformation:

$$x(t) = (1/2\pi) \int_{-\infty}^{\infty} X(k) e^{jkt} dk \quad (3)$$

If $x(t)$ is not a continuous function but has a finite number values ($x_0, x_1, x_2, \dots, x_{N-1}$) at finite time $i = 0$ to $i = N-1$ having sampling interval Δt , then the Fourier transform X_m at discrete frequencies $f_m = m/N\Delta t$ is called the discrete Fourier transform (DFT):

$$X_m = (1/N) \sum_{i=0}^{N-1} x_i e^{-j(2\pi mi/N)} \text{ for } m = 0, \dots, N-1 \quad (4)$$

The quantity X_m is a complex number having real and imaginary components. Most of the time, we use power spectral density ($P(k)$), which is defined as the square of amplitude of the DFT:

$$P(k) = (1/N) \sum_{m=0}^{N-1} |X_m|^2 \quad (5)$$

The calculation of power spectral density from the data using the DFT is called the periodogram method. Cooley and Tukey (1965) introduced a fast algorithm to calculate the Fourier transform, called the fast Fourier transform (FFT). The other popular method, known as the Blackman and Tukey method (Blackman and Tukey 1958), calculates the power spectral density from the autocorrelation function based on Wiener-Khintchine theorem. Blackman and Tukey's approach is also useful for estimating power spectral density of random distribution when inequality condition of Eq. (1) is not met. The other high-resolution methods, e.g., Maximum Entropy Method (MEM) (Burg 1967) and Maximum Likelihood Method (MLM) (Capon et al. 1967), and multi-Taper Method (MTM) (Thomson 1982) can also be applied to calculate the power spectral density (Dimri 1992).

Application of Power Spectral Density (PSD)

Correlation of Space/Time Series

The power spectral density is also useful for understanding the behavior of a time/space series. The random and uncorrelated time/space series are also known as white noises. The white noises have contents of all frequencies, e.g., the slope of a fitted straight line in the plot of log frequency/wavenumber versus plot of power spectral density equals zero. The white noise series' autocorrelation has only a finite value at zero lag and zero values at other lags. However, a time/space series are often not white noises but are correlated and known as scaling noises. The power spectral density of scaling noises is frequency-dependent. The slope of a straight line fitted to the log of frequency/wavenumber versus the log of power spectral density defines the series' correlation. The higher the value of slope higher is the correlation of time/space series. Recent measurements from the boreholes have shown the distribution of physical properties in the subsurface as scaling (Bansal and Dimri 2014). The white noise distribution assumption is away from reality and it was assumed so because of mathematical simplicity and unknown information about detailed distribution of physical properties within the

crust. The scaling noises find many applications in the interpretation of geophysical data, e.g., depth estimation from gravity and magnetic data, regional residual separation of gravity and magnetic measurements, inversion of geophysical data, predictive deconvolution, ore deposits, and earthquake distribution in space and time (Turcotte 1997).

The scaling noises' power spectral density is expressed as $P(k) \propto k^\beta$, where $P(k)$, k , and β are power spectral density, wavenumber, and scaling exponent. The value of the scaling exponent equal to zero represents the white noise. The scaling exponent can be further related to the fractal dimension (D), valid for β between 1 and 3.

$$\beta = 5 - 2D \quad (8)$$

The scaling noises can be further related to fractional Gaussian and Brownian walks. The scaling noises are also useful for defining a self-similar or self-affine fractal (Turcotte 1997).

Estimation of Density/Susceptibility Distribution from Gravity and Magnetic Observations

The Fourier series analysis of space/time series is useful to solve some of the mathematical functions like convolution/deconvolution. For a linear system, the convolution operator is useful to find an output ($y(t)$) from the input signal ($x(t)$) and earth's response ($h(t)$). The convolution operator for a discrete case is defined:

$$y_t = \sum_i x_i h_{t-i} \quad (6)$$

These convolution operators exist almost in all geophysical studies. We want to study the output by sending a known input, e.g., estimating gravity/magnetic potential from the density distribution and structural function.

In the frequency domain, the convolution of gravity/magnetic potentials (Eq. 6) is converted in the form of multiplication using the well-known convolution theorem as:

$$U_g(f) = \rho(f) R(f) \quad (7)$$

where $U_g(f)$ is the Fourier transform of the gravity/magnetic potential, $\rho(f)$ is the Fourier transform of the density/susceptibility distribution, and $R(f)$ is the Fourier transform of Geometric function. In other words, the Fourier transform of gravity/magnetic potential is a combination of two multiplicative factors: (1) a function of depth and thickness, and (2) a function of distribution of density/susceptibility (Blakely 1995).

Depth Estimation from Gravity and Magnetic Data

The estimation of the depth of anomalous sources from the gravity/magnetic measurements in spectral methods expressed for a white noise distribution of sources as (Spector and Grant 1970):

$$P(k) = Ae^{-2dk} \quad (9)$$

The white noise distribution of sources provides an over-estimation of anomalous sources' depths (Bansal and Dimri 2001, 2014). The scaling noise distribution of sources resulted in the modification of the above equation as:

$$P(k) = Bk^{-\beta}e^{-2kd} \quad (10)$$

The depth estimations for the scaling distribution of sources are found close to reality. The scaling distribution of sources found many applications in estimating the depth of anomalous sources from gravity and magnetic measurements from different parts of the world.

Upward and Downward Continuation

The gravity and magnetic measurements are carried out on the Earth's surface, at a ship on the sea, air-borne surveys at sea and land, or measured at satellite elevation. These measurements are at different heights. To bring these measurements at the same elevations, frequently upward continuation of the measured data is carried out. The other advantage of upward continuation is attenuating near-surface anomalies and enhancing the more resonant anomalies at the expense of near-surface anomalies. The downward continuation is carried out to enhance the effect of the shallower bodies as compared to the upward continuation. The upward continuation is smoothing operation whereas downward continuation is unsmoothing operation (Blakely 1995). A small noise in the data causes large variations during the downward continuation. The computation of upward continuation is complicated in the space domain where these become multiplication with the exponential term and Fourier transform of the measured field. Again we can bring back the field in space domain by taking inverse transforms.

Summary and Conclusions

The power spectral density found wide applications to understand the correlation of time series, estimation of density/susceptibility distribution within the crust, depth estimation

from gravity and magnetic data, and downward and upward continuation of potential field data.

Predictive Geologic Mapping and Mineral Exploration

Frits Agterberg
Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Definition

During the nineteenth century and most of the twentieth century, the geology map was the most important tool for mineral exploration. More recently, the emphasis to find new mineral deposits has shifted to the use of geophysical and geochemical methods. Nevertheless, the geologic map augmented by remote sensing at the surface of the Earth and the use of exploratory boreholes remains indispensable for target selection in mineral exploration. In this chapter, the emphasis will be on lesser known but potentially powerful new methods of predictive geologic mapping for mineral exploration, because the subject is also covered in other chapters.

Introduction

The first geologic map was published in 1815. This feat has been well documented by Winchester (2001) in his book: *The Map that Changed the World – William Smith and the Birth of Modern Geology*. According to the concept of stratigraphy, strata were deposited successively in the course of geologic time, and they are often uniquely characterized by fossils such as ammonites that are strikingly different from age to age. Additionally, there are different types of igneous and metamorphic rocks. Geologic maps turned out to be essential tools for mineral exploration. For example, during the nineteenth century, coal became important in England and other countries. Its occurrence is largely restricted to the Carboniferous Period, which occurs in many different countries and is readily recognizable in outcrops at the surface of the Earth, although it covers only a small portion of the total surface area in the regions where it occurs. Today different countries in the world have fairly complete geological maps synchronized according to international standards (*cf.* portal.oneygeology.org).

It is remarkable that the usefulness of geologic maps remained virtually unknown until approximately 1800. There are many other examples of geologic concepts that became only gradually accepted more widely, although they usually had been proposed much earlier in one form or another by individual scientists. The best-known example is plate tectonics: Alfred Wegener (1966) had demonstrated the concept of continental drift fairly convincingly as early as 1912 but this idea only became acceptable in the early 1960s. One reason that this theory initially was rejected by most geoscientists was the lack of a plausible mechanism for the movement of continents. It is important to keep in mind that geologic maps are two-dimensional and our ability to extrapolate downward from the surface of the Earth to create three-dimensional realities is severely limited. Rocks were formed at different times by means of different processes. Thus, a single internationally accepted geologic time scale is important (*cf.* Gradstein et al. 2020) in addition to sound geoscientific theory. The following two examples illustrate some of the difficulties originally and currently experienced in creating 3D geologic realities by downward extrapolation using data observed at the surface of the Earth.

Harrison (1963) has pointed out that, although the outcrops in an area remain more or less the same in the immediate past, a geologic map constructed from them can change significantly over time when new geoscientific concepts become available. A striking example is shown in Fig. 1. Over a 30-year period, the exposed bedrock in this study area on the Canadian Shield that was repeatedly visited by geologists had remained nearly unchanged. However, the geologic maps and their legends created by different geologists are entirely different. These discrepancies reflect

Predictive Geologic Mapping and Mineral Exploration, Fig. 1 Two geologic maps for the same area on the Canadian Shield published at different times. As pointed out by Harrison (1963), between 1928 (a) and 1958 (b) there was development of conceptual ideas about

the nature of metamorphic processes that resulted in geologists constructing different maps based on same observations (Source: Agterberg 2014, Fig. 1)

changes in the state of geologic knowledge at different points in time. In another example (Fig. 2), according to Nieuwenkamp (1968), a typical downward extrapolation problem is shown with results strongly depending on initially erroneous theoretical considerations. In the Kinnehulle area in Sweden, the tops of the hills consist of basaltic rocks; sedimentary rocks are exposed on the slopes and granites and gneisses in the valleys. The first projections into depth for this

area were made by a prominent geologist (Von Buch 1842). It can be assumed that today most geologists would quickly arrive at the third 3D reconstruction (Fig. 2c) by Westergård et al. (1943). At the time of von Buch, it was not yet common knowledge that basaltic flows can form extensive flat plates within sedimentary sequences.

The projections in Fig. 2a and b reflect A.G. Werner's pan-sedimentary theory of "Neptunism" according to which all

Predictive Geologic Mapping and Mineral Exploration, Fig. 2 Geological observations made at the surface of the Earth have to be extrapolated downwards in order to obtain a full 3-dimensional representation of reality. This can be an error prone process as pointed out by Nieuwenkamp (1968). Sections **a** and **b** for an area in Sweden are modified after von Buch (1842) illustrating his genetic interpretation that

rocks on Earth were deposited in a primeval ocean. Nieuwenkamp (1968) demonstrated that this theory was related to the philosophical concepts of F.W.J. Schelling and G.W.F. Hegel. When Werner's view was criticized by other early geologists who assumed processes of change took place during geologic time, Hegel publicly supported Werner by comparing the structure of the Earth with that of a house. One looks at the complete house only, and it is trivial that the basement was constructed first and the roof last. Initially, Werner's conceptual model provided an appropriate and temporarily adequate classification system, although von Buch, who was a student of Werner, rapidly ran into problems during his attempts to apply Neptunism to explain the occurrences of rock formations in different parts of Europe. For the Kinnehulle area (Fig. 2), von Buch assumed that the primeval granite became active later changing sediments into gneisses, while the primeval basalt became a source for hypothetical volcanoes.

Probably the most important usage of geologic maps is that they can be used to delineate target areas for the discovery of new mineral deposits by drilling boreholes in places with a relatively high probability of success in such discovery. In addition to the geologic maps, frequent use is made of remote sensing and geophysical and geochemical data. These types of information also can be used to estimate the mineral potential of larger areas, i.e., total number of undiscovered mineral deposits of different types. In the following sections, the

was based on combining Werner's original theory of Neptunism with von Buch's own firsthand knowledge of volcanoes including Mount Etna in Sicily with a basaltic magma chamber. He was not aware of the fact that basaltic flows can be widespread covering large areas, the genetic model used by Westergård et al. (1943) for constructing Section **c** (Source: Agterberg 1974, Fig. 1)

topics to be discussed are (1) the use of multivariate statistical methods to estimate the probability of occurrence of mineral deposits; (2) use of jackknife method to reduce bias instead of defining "control" areas; (3) weights-of-evidence (WofE) method; and (4) singularity analysis. Topics (3) and (4) are well covered in other chapters and will only be briefly discussed in this chapter.

Mineral Potential Maps

An early example of regional resource prediction is shown in Fig. 3 (from Agterberg and David 1979). Amounts of copper in existing mines and prospects had been related to lithological and geophysical data in the Abitibi area on the Canadian Shield to construct copper and zinc potential maps (Agterberg et al. 1972). During the 1970s there was extensive mineral exploration for these metals in this region that resulted in the discovery of seven new large copper deposits shown in black on Fig. 3. This example illustrates some of the advantages and drawbacks of the application of statistical techniques to predict regional mineral potential from geoscience map data. The later discoveries in the Abitibi area fit in with the prognostic contour pattern that was based on the earlier (pre-1968) discovered copper deposits (open circles in Fig. 3).

The prognostic contours in Fig. 3 are for the estimated number of (10 × 10 km) "control cells" with known copper

Predictive Geologic Mapping and Mineral Exploration, Fig. 3 Copper potential map, Abitibi area on the Canadian Shield. Contours and deposit locations are from Agterberg et al. (1972). Contour

deposits within 16 times larger (40×40 km) cells. When the contour map was constructed in 1972, there were 27 control cells. The probability that any ($10 \text{ km} \times 10 \text{ km}$) cell in the study area would contain one or more mineable copper deposits was assumed to satisfy a Bernoulli random variable with parameter p . Any contour value on the map therefore can be regarded as the mean $x = n \cdot p$ of a binomial distribution with variance $n \cdot p \cdot (1-p)$ where $n = 16$. The corresponding amount of copper would be the sum of x values drawn at random from the exceedingly skewed size-frequency distribution for amounts of copper in the 27 control cells. The resulting uncertainty for most contour values therefore was and remains exceedingly large.

The probabilities p for the 644 ($10 \text{ km} \times 10 \text{ km}$) cells used for the example of Fig. 3 were estimated by stepwise multiple regression (Draper and Smith 1966). The value of the dependent variable for the 27 control cells out of the 644 ($10 \text{ km} \times 10 \text{ km}$) cells used was set equal to the logarithm (base 10) of the total amount of copper per control cell and equal to zero for the ($644 - 27 =$) 617 cells without, known in 1968, copper deposits. A total of 55 geological and geophysical variables were used as independent variables in this application of which 26 were retained after using the stepwise regression method. Figure 4 illustrates that simple binary combinations of the independent variables used can already show a pattern that is positively correlated with the pattern of the control cells.

Initial estimates of the dependent variable were biased because of probable occurrences of undiscovered deposits in many of the ($10 \text{ km} \times 10 \text{ km}$) cells that had been less explored. This bias was corrected by multiplying all initial

value represents expected number of ($10 \text{ km} \times 10 \text{ km}$) cells per ($40 \text{ km} \times 40 \text{ km}$) unit area containing one or more copper ore deposits (Source: Agterberg and David 1979)

estimates by a factor $F = 2.35$ representing the sum of all observed values divided by the sum of the corresponding initial estimates within a well-explored area consisting of 50 cells within the Timmins and Noranda-Rouyn mining camps jointly used as a “control area.” The total amount of mined or mineable copper contained in the entire study area (used to construct Fig. 3) amounted to 3.12 million tons. Multiplication of this amount by $F = 2.35$ gave 7.33 million tons as an estimate of the total amount of copper in the entire study area. After 9 years of intensive exploration subsequent to the construction of the contours in Fig. 3, 5.23 million tons of this hypothetical total had been discovered (*cf.* Agterberg and David 1979).

The metal potential maps published by Agterberg et al. (1972) created a significant amount of discussion in the scientific literature of which three publications will be briefly discussed here. Tukey (1972) suggested that, since probabilities cannot be negative or greater than 1, logistic regression should be considered as an alternative to using the general linear model in studies of this type. This suggestion was followed up in Agterberg (1984) for (A) copper in volcanogenic massive sulfide deposits and (B) nickel in magmatic nickel-copper deposits in a larger part of the Canadian Shield that includes the area used for Fig. 3 (see Fig. 5). The two types of copper deposits (A and B) were analyzed separately because they have different origins (*cf.* Pirajno 2010). Within the smaller Abitibi area, the pattern in Fig. 5a resembles that of the original copper potential map (Fig. 3). This is because the number of volcanogenic massive sulfide deposits significantly exceeds the number of magmatic nickel-copper deposits in this region. The general linear model failed to

Predictive Geologic Mapping and Mineral Exploration, Fig. 4 The Abitibi area on the Canadian Shield in the provinces of Ontario and Quebec had been subdivided into 643 (10 km × 10 km) cells. Top diagram (a) shows 27 copper-deposit rich cells with estimated tonnages of copper (rounded values of logarithm (base 10)). Bottom

diagram (b) shows cells with co-occurrence of acid volcanics and Bouguer anomaly above average. The two patterns are strongly correlated indicating that copper deposits tend to occur in places where acid volcanics occur on top of basic volcanics with relatively high specific gravity (Source: Agterberg 1974, Fig. 119)

produce meaningful mineral potential contours for the relatively few magmatic nickel-copper deposits that are closely associated with mafic and ultramafic intrusions on the Canadian Shield (Agterberg 1974). This was because relatively many estimated probabilities fell out outside the [0,1] interval. Thus, for relatively rare types of deposits, logistic regression produces better results than ordinary multiple regression.

Wellmer (1983) pointed out that one of the seven new discoveries shown in Fig. 3 is the Timmins nickel-copper deposit with 3,500,000 tons of ore. It is a magmatic nickel-copper deposit and not a volcanogenic massive sulfide deposit discovered in 1976 that occurs on the westernmost peak in Fig. 3 which was delineated in 1972, relatively far away from any earlier discovered copper deposits in the Abitibi area. Since this peak is not clearly delineated in Fig. 5b obtained by logistic regression in 1974, this indicates that the general linear model locally can produce better results than logistic regression. Its final result can be regarded simply as the sum of 27 separate copper potential evaluations each based on

information for a single control cell only. This property of the general linear model is important because it allows the estimation of probable occurrences of mineral deposits that are of different genetic types. Finally, in another discussion paper, Tukey (1984) pointed out that on the peaks of maximal copper potential in Fig. 3, the known copper deposits tend to occur on the flanks of the peaks instead of in their centers. This observation was confirmed by a statistical significance test Agterberg (1984), but a geoscientific explanation of this feature has not yet been found.

Bias and the Jackknife

In order to compare various geoscientific trend surface and kriging applications with one another, Agterberg (1970) had randomly divided the input data set for a study area used for example into three subsets: Two of these subsets were used for control and results derived for the two control sets were

Predictive Geologic Mapping and Mineral Exploration, Fig. 5 Occurrences of (a) copper-zinc deposits, and (b) magmatic nickel-copper deposits in (40 km × 40 km) cells on part of the Precambrian Canadian Shield. was used to estimate The underlying probabilities for (10 km × 10 km) cells were estimated by logistic instead of linear regression for an area larger than that used for Fig. 4. Note the similarity of pattern for the central part of (a) with the pattern of Fig. 4. Logistic regression gave better results than linear regression for relatively few of the nickel-copper deposits of (b) (Source: Agterberg 1984, Fig. 3)

then applied to a third “blind” subset in order to see how well results for the control subsets could predict the values in the third subset. In his comments on this approach, Tukey (1970) stated that this form of cross-validation could indeed be used but a better technique would be to use the then newly proposed Jackknife method. The following brief explanation of this method is based on Efron (1982). In geoscientific mineral potential applications, it can help to eliminate bias due to great variations in the regional intensity of exploration, a problem

that in the previous section was solved by defining a control area consisting of well-explored mining camps (bias factor $F = 2.35$ in Abitibi area).

For cross-validation it has become common practice to leave out one data point (or a small number of data points) at a time and fit the model using the remaining points to see how well the reduced data set does at the excluded point (or set of points). The average of all prediction errors then provides the cross-validated measure of the prediction error. Cross-validation, the jackknife, and bootstrap are three techniques that are closely related. Efron (1982), Chapter 7) discusses their relationships in a regression context pointing out that, although the three methods are close in theory, they generally yield different results in practical applications. The following application was previously described in Agterberg (2021).

For a set of n independent and identically distributed (*iid*) data, the standard deviation of the sample mean ($\bar{x}$) satisfies $\hat{\sigma}(\bar{x}) = \sqrt{\frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n(n-1)}}$. This result cannot be extended to other estimators such as the median. However, the jackknife and bootstrap can be used to make this type of extension. Suppose $\bar{x}_i = \frac{n\bar{x} - x_i}{n-1}$ represents the sample average of the same data set but with the data point x_i deleted. Let $\bar{x}_{JK}$ represent the mean of the n new values $\bar{x}_i$. The jackknife estimate of the standard deviation then is $\hat{\sigma}_{JK} = \sqrt{\frac{(n-1) \sum_{i=1}^n (\bar{x}_i - \bar{x}_{JK})^2}{n}}$, and it is easy to show that $\bar{x}_{JK} = \bar{x}$ and $\sigma_{JK} = \sigma(\bar{x})$.

The jackknife was originally invented by Quenouille (1949) under another name and with the purpose to obtain a nonparametric estimate of bias associated with some types of estimators. Bias can be formally defined as $BIAS \equiv E_F\{\vartheta(\hat{F})\} - \vartheta(F)$ where E_F denotes expectation under the assumption that n quantities were drawn from an unknown probability distribution F ; $\hat{\vartheta} = \vartheta(\hat{F})$ is the estimate of a parameter of interest with $\hat{F}$ representing the empirical probability distribution. Quenouille’s bias estimate (*cf.* Efron 1982, p. 5) is based on sequentially deleting values x_i from a sample of n values to generate different empirical probability distributions $\hat{F}_i$ each based on $(n-1)$ values resulting in the estimates $\hat{\vartheta}_i = \vartheta(\hat{F}_i)$. Writing $\bar{\vartheta} = \frac{\sum_{i=1}^n \hat{\vartheta}_i}{n}$, Quenouille’s bias estimate then becomes $(n-1) \cdot (\bar{\vartheta} - \hat{\vartheta})$, and the bias-corrected “jackknifed estimate” of ϑ is $\tilde{\vartheta} = n\bar{\vartheta} - (n-1)\hat{\vartheta}$. This estimate is either unbiased or less biased than $\hat{\vartheta}$.

Examples of Jackknife Applications in Regional Mineral Potential Estimation

A very simple example of application to a hypothetical mineral resource estimation problem is as follows. Suppose that half of a study area consisting of 100 equal-area cells is well-explored and that two mineral deposits have been discovered

in it. This 50-cell “control area” can be used to estimate the number of undiscovered deposits in the 50-cell “target area” representing the other half of the study area that is relatively unexplored. Suppose further that the mineral deposits of interest are contained within a “favorable” rock type that occurs in 5 cells of the control area as well as in 5 cells of the target area. Because 2 of these 5 cells in the control area are known to contain a known ore deposit of interest, it is reasonable to assume that the target area would contain 2 undiscovered deposits as well. Thus, the entire study area probably contains 4 deposits. Obviously, it would not be good to assume that it contains only two deposits which constitutes a severely biased estimate.

Application of the “leave-one-out” jackknife method to the 50-cell study area results in two biased estimates that are both equal to a single deposit. This also translates into the biased prediction of two deposits in the entire study area. By using the jackknife theory summarized in the preceding section, it is quickly shown that the jackknifed bias in this biased estimate also is equal to two deposits. The use of the jackknife for the

study area, therefore, results in four deposits of which the two undiscovered deposits would occur within the cells with favorable rock type in the target area.

A second, more realistic example is shown in Fig. 6. The top diagram (Fig. 6a) is for the same study area that was used for Fig. 3, but the contour values in Fig. 6 are for smaller ($30 \text{ km} \times 30 \text{ km}$) squares. The bottom diagram (Fig. 6b) shows a result obtained by using the jackknife method that produces nearly the same pattern. For both Figs. 3 and 6a, the contour values were obtained by multiple regression in which the dependent variable was the amount of copper per cell and the explanatory variables consisted of lithological composition and geophysical data as discussed previously.

For the application of the jackknife (Agterberg 1973), the 35 control cells in the study area were divided into 7 groups each consisting of 5 cells, and these groups were deleted successively to obtain the 7 biased estimates required, with the final jackknife estimate shown in Fig. 6b, which is almost the same as Fig. 6a. The fact that two different approaches produced similar results indicates that both

Predictive Geologic Mapping and Mineral Exploration, Fig. 6 (a and b) Comparison of copper potential maps for ($30 \text{ km} \times 30 \text{ km}$) cells in the Abitibi area derived by (a) ordinary multiple regression using a

“control area” with $F = 1.828$, and (b) the jackknife method without the assumption of existence of a “control area” (Source: Agterberg 1973, Fig. 4)

Predictive Geologic Mapping and Mineral Exploration, Fig. 7 Expected total amounts of copper for ore-rich cells predicted in Fig. 6a. Contour values are logarithms (base 10) for (30 km × 30 km) unit cells (Source: Agterberg 1973, Fig. 5a)

methods of prediction of undiscovered copper resources are probably valid. The two methods also yield similar estimates for the probabilities of cells as is illustrated in Table 1 (see Agterberg 2014, for the exact locations of these cells). Standard deviations equal to $\{p \cdot (1 - p)\}^{0.5}$ estimated by the jackknife method are shown in the last column of Table 1. It is noted that one of the estimated jackknife probabilities is negative, although it is not significantly less than 0. Problems of this type can be avoided by using logistic regression. However, the general linear model used to estimate probabilities in this kind of application can have relative advantages (*cf.* Agterberg 2014).

Estimating Total Amounts of Metal from Mineral Potential Maps

In a study described in Agterberg (1973), the Abitibi study area contained 35 (10 km × 10 km) cells with one or more large copper deposits. Two types of multiple regressions were carried out with the same explanatory variables. First the

dependent variable was set equal to 1 in the 35 control cells, and then it was set equal to a logarithmic measure (base 10) of short tons of copper per control cell. Suppose that estimated values for the first regression are written as P_i and those for the second regression as Y_i . Both sets of values were added for overlapping square blocks of cells to obtain estimates of expected values (30 km × 30 km) unit cells. In Fig. 7 the ratio $Y_i^* = Y_i / P_i$ is shown as a pattern that is superimposed on the pattern for the P_i values only. The values of Y_i^* cannot be estimated when Y_i and P_i are both close to zero. Little is known about the precision of Y_i^* for $P_i \geq 0.5$. These values (Y_i^*) should be transformed into estimated amounts of copper per cell here written as X_i . Because of the extreme positive skewness of the size-frequency distribution for amounts of copper per cell (X_i), antilogs (base 10) of the values of Y_i^* as observed in control cells only were multiplied by the constant $c = \sum X_i / \sum 10^{Y_i}$ in order to reduce bias under the assumption of approximate lognormality. The pattern of Fig. 7 is useful as a suggested outline of subareas where the largest volcanogenic massive sulfide deposits are more likely to occur.

Weights-of-Evidence Modeling

Weights-of-evidence modeling is a technique to predict the occurrence of discrete events such as mineral deposits, landslides, or earthquakes from digital geoscience map data. The statistical approach in this method was originally based on the approach taken by Spiegelhalter and Knill-Jones (1984) in their medical GLADYS expert system (*cf.* Agterberg 1989). WofE became widely used by mineral exploration companies and other organizations after the publication of Bonham-Carter (1994)'s book entitled *Geographic information systems for geoscientists: modeling with GIS*. Since the approach is covered in other chapters, the discussion in this section will be restricted to basic principles and a single example of an early application to gold deposits in Nova Scotia (Bonham-Carter et al. 1988).

Suppose that occurrences of mineralization, coded as 1 for presence and 0 for absence in a map pattern called D , are to be related to a single map layer that is available in digital form. When there is a single map pattern B , the odds $O(D|B)$ for the occurrence of mineralization if B is present is given by the ratio of the following two expressions of Bayes' rule:

$$P(D|B) = \frac{P(B|D)P(D)}{P(B)}; P(\bar{D}|B) = \frac{P(B|\bar{D})P(\bar{D})}{P(B)} \text{ where the set } \bar{D}$$

represents the complement of D . Consequently, $\ln O(D|B) = \ln O(D) + W^+$ where the positive weight for presence of B is $W^+ = \ln \frac{P(B|D)}{P(B|\bar{D})}$. The negative weight for the absence of B is $W^- = \ln \frac{P(\bar{B}|D)}{P(\bar{B}|\bar{D})}$. When there are two map patterns: $P(D|B \cap C) = \frac{P(B \cap C|D)P(D)}{P(B \cap C)}$; $P(\bar{D}|B \cap C) = \frac{P(B \cap C|\bar{D})P(\bar{D})}{P(B \cap C)}$. Conditional independence of D with respect to B and C implies:

$$P(B \cap C|D) = P(B|D)P(C|D); P(B \cap C|\bar{D}) = P(B|\bar{D})P(C|\bar{D}).$$

Consequently, $P(D|B \cap C) = P(D) \frac{P(B|D)P(C|D)}{P(B \cap C)}$; $P(\bar{D}|B \cap C) = P(\bar{D}) \frac{P(B|\bar{D})P(C|\bar{D})}{P(B \cap C)}$.

From these two equations, it follows that $\frac{P(D|B \cap C)}{P(\bar{D}|B \cap C)} = \frac{P(D)P(B|D)P(C|D)}{P(\bar{D})P(B|\bar{D})P(C|\bar{D})}$. This expression is equivalent to $\ln O(D|B \cap C) = \ln O(D) + W_1^+ + W_2^+$. The posterior logit on the left of this expression is the sum of the prior logit and the weights of the two map layers. The approach is only valid if the map layers are wholly or conditionally independent, and this hypothesis should be tested in applications. The approach can be extended to include other map layers. Various conditional independence tests have been developed (see, e.g., Agterberg 2014). Approximate variances of the weights can be obtained from:

$$\sigma^2(W^+) = \frac{1}{n(bd)} + \frac{1}{n(\bar{b}\bar{d})}; \sigma^2(W^-) = \frac{1}{n(b\bar{d})} + \frac{1}{n(\bar{b}d)}$$

where the denominators of the terms on the right sides represent numbers $n(\cdot)$ of unit cells with map layer and

deposit present or absent. Spiegelhalter and Knill-Jones (1984) had used similar asymptotic expressions for variances of weights in their GLADYS expert system. Using $p(\cdot)$ to denote probabilities, the following contingency table can be created:

$$P = \begin{bmatrix} p(bd) & p(b\bar{d}) \\ p(\bar{b}d) & p(\bar{b}\bar{d}) \end{bmatrix} \equiv \begin{bmatrix} n(bd)/n & n(b\bar{d})/n \\ n(\bar{b}d)/n & n(\bar{b}\bar{d})/n \end{bmatrix}$$

If there is no spatial correlation between deposit points and map pattern:

$$P = \begin{bmatrix} p(b) \cdot p(d) & p(b) \cdot p(\bar{d}) \\ p(\bar{b}) \cdot p(d) & p(\bar{b}) \cdot p(\bar{d}) \end{bmatrix}$$

where $p(b)$ is the proportion of study area occupied by map layer B and $p(d)$ is the total number of deposits divided by total area, and with similar explanations for the other proportions. A chi-square test for goodness of fit can be applied to test the hypothesis that there is no spatial correlation between deposit points and map using pattern. It is equivalent to using the z -test to be described in the next paragraph. The variance of the "contrast" C is:

$$\sigma^2(C) = \frac{1}{n(bd)} + \frac{1}{n(b\bar{d})} + \frac{1}{n(\bar{b}d)} + \frac{1}{n(\bar{b}\bar{d})}.$$

One of the first WofE applications is 68 gold deposits in a study area of 2,591 km² in Nova Scotia (Bonham-Carter et al. 1988). Weights, contrasts, and their standard deviations for nine map patterns used in Bonham-Carter et al. (1988) for this same study area are shown in Table 2. The last column in this table is the "studentized" value of C , for testing the hypothesis that $C = 0$. Values greater than 1.96 indicate that this hypothesis can be rejected at a level of significance $\alpha = 0.05$. For more information on the validity of the conditional independence tests, see Agterberg (2014). For an alternative approach to solve the same type of problem, see Baddeley et al. (2021).

Figure 8 shows the posterior probability map using the weights of Table 2. Some of the areas with the largest posterior probabilities contain known gold deposits but others do not. These other areas are of interest for further exploration, because they may contain undiscovered gold deposits (*cf.* Bonham-Carter et al. 1990). Gold production and reserved figures were available for the 68 gold deposits used as input for this study. Figure 9 is a plot of posterior probability against cumulative area showing gold mines that were producing in 1990 as circles whose radii reflect magnitudes of production in 1990. There appears to be a positive correlation between production and posterior probability.

Local Singularity Analysis

This last section is devoted to a relatively new method called “local singularity analysis” developed by Cheng (1999, 2005, 2008) for geochemical or other data systematically collected across large study areas. Local singularity analysis, which has become important for helping to predict occurrences of hidden ore deposits, is based on the multifractal equation $x = c \cdot \epsilon^{\alpha-E}$ where x represents the element concentration value, c is a constant, α is the singularity, ϵ is a

normalized distance measure such as square grid cell edge, and E is the Euclidian dimension. The theory of singularity is given in other chapters. Here it will be assumed that $E = 2$ and that chemical element concentration values are available for small square grid cells of which the spatial autocorrelation function (or variogram) is largely determined by its behavior near the origin, which is difficult to establish by earlier statistical or geostatistical techniques. For a relatively simple discussion of singularity analysis, also see de Mulder et al. (2016).

Predictive Geologic Mapping and Mineral Exploration, Fig. 9 Posterior probability as shown in Fig. 8 plotted against cumulative area, with producing gold mines shown as circles with radii reflecting magnitudes of reported production (Source: Bonham-Carter et al. 1990, Fig. 4)

In Cheng's (1999, 2005) original approach, geochemical or other data collected at sampling points within a study area are subjected to two treatments. The first of these is to construct a contour map by any of the methods such as kriging or inverse distance weighting techniques generally used for this purpose. Secondly, the same data are subjected to local singularity mapping. The local singularity α then is used to enhance the contour map by multiplication of the contour value by the factor $\epsilon^{-\alpha/2}$ where $\epsilon < 1$ represents a length measure. In Cheng's (2005) application to predictive mapping, the factor $\epsilon^{-\alpha/2}$ is greater than 2 in places where there has been local element enrichment or by a factor less than 2 where there has been local depletion. Local singularity mapping can be useful for the detection of geochemical anomalies characterized by local enrichment even if contour maps for representing average variability are not constructed (cf. Cheng and Agterberg 2009; Zuo et al. 2009).

Gejiu Mineral District and Northwestern Zhejiang Province Examples

Where the landscape permits this, stream sediments are the preferred sampling medium for reconnaissance geochemical

surveys concerned with mineral exploration (Plant and Hale 1994). During the 1980s and 1990s, government-sponsored reconnaissance surveys covering large parts of Austria, the Canadian Cordillera, China, Germany, South Africa, the UK, and the USA were based on stream sediments (Darnley et al. 1995). These large-scale national projects, which were part of an international geochemical mapping project (Darnley 1995), generated vast amounts of data and continue to be a rich source of information. Cheng and Agterberg (2009) applied singularity analysis to data from about 7800 stream sediment samples collected as part of the Chinese regional geochemistry reconnaissance project (Xie et al. 1997). For illustration, about 1000 stream sediment tin concentration values from the Gejiu area in Yunnan Province were used.

The study in this first example has an area of about 4000 km² and contains 11 large tin deposits. Several of these, including the Laochang and Kafang deposits, which are tin-producing mines with copper extracted as a by-product. These hydrothermal mineral deposits also are enriched in other chemical elements including silver, arsenic, gold, cadmium, cobalt, iron, nickel, lead, and zinc. The application to be described here is restricted to arsenic which is a highly toxic element. Water pollution due to high arsenic, lead, and cadmium concentration values is considered to present one of the most serious health problems especially in underdeveloped areas where mining is the primary industry such as in parts of the Gejiu area. Knowledge of the characteristics of the spatial distribution of ore elements and associated toxic elements in surface media is helpful for the planning of mineral exploration as well as environmental protection strategies.

The Gejiu mineral district (Fig. 10) is located along the suture zone of the Indian Plate and Euro-Asian plates on the southwestern edge of the China subplate, approximately 200 km south of Kunming, capital of Yunnan Province, China. The Gejiu Batholith with outcrop area of about 450 km² is believed to have played an important role in the genesis of the tin deposits (Yu 2002). The ore deposits are concentrated along intersections of NNE-SSW and E-W trending faults. Stream sediment sample locations in the Gejiu area are equally spaced at approximately 2 km in the north-south and east-west directions. Every sample represents a composite of materials from the drainage basin upstream of the collection site (Plant and Hale 1994).

Regional trends were captured in a moving average map of tin concentration values from within square cells measuring 26 km on a side. Several parameters have to be set for use of the inverse distance weighted moving average method (Cheng 2003). In the current application, each square represented the moving average for a square window measuring 26 km on a side with an influence of

Predictive Geologic Mapping and Mineral Exploration, Fig. 10 Map patterns derived from arsenic concentration values in 1,000 stream sediment samples in Gejiu Mineral District, Yunnan Province, China. Large tin deposits are shown as white triangles. Pattern (a) shows distribution of arsenic concentration values using inverse distance weighted moving average; pattern (b) shows distribution of local tin singularities (a). The 3 tin deposits outside the highly polluted mining area shown in pattern (a) are recent discoveries. All 11 large tin deposits occur in places where local anomaly in pattern (b) is less than 2 (Source: Cheng and Agterberg 2009, Fig. 1)

samples decreasing with distance according to a power-law function with exponent set equal to -2 . Original sample locations were 2 km apart both in the north-south and east-west directions. The resulting map (Fig. 10a) shows a large anomaly in the eastern part of the Gejiu area surrounding the most large tin deposits including the mines. The three large tin deposits in the central part of the Gejiu area are recent discoveries that have not yet been mined. To illustrate in more detail how singularities were estimated, see Cheng and Agterberg (2009). The singularities were estimated by fitting straight lines on log-log plots of either the concentration value (x) versus ϵ using $x = c \cdot \epsilon^{-\alpha/2}$ or amount of metal $\mu = x \cdot \epsilon^{-2}$ versus ϵ using $\mu = c \cdot \epsilon^{\alpha}$. Both methods yielded similar estimates of the singularity α . Figure 10b shows results using the first method only. The main difference between the patterns of Fig. 10a and b is that lower and

higher local As singularity values are more evenly distributed across the Gejiu area than the As concentration values themselves. Similar results were obtained for other elements including tin (see Cheng and Agterberg 2009). Clearly, Fig. 10b provides a better guideline for finding unknown large tin deposits than Fig. 10a. On the other hand, Fig. 10a more clearly shows the area in which the streams are highly polluted because of mining pollution over an extended period of time.

The second example shown in Figs. 11 and 12 (after Xiao et al. 2012) is for lead in northwestern Zhejiang Province, China, that in recent years has become recognized as an important polymetallic mineralization area with the discovery of several moderate to large Ag and Pb-Zn deposits mainly concentrated along the northwestern edge of the study area (Fig. 11), which has been relatively well explored. The pattern of local singularities based on Pb in stream sediment samples is spatially correlated with the known mineral deposits. It can be assumed that similar anomalies in parts of the less explored parts of the area provide new targets for further mineral exploration (Fig. 12). By combining singularities for different chemical elements with one another, spatial correlation between anomalies and mineral deposits can be further increased (Xiao et al. 2012).

Summary and Conclusions

Geologic maps augmented by remote sensing and geophysical and geochemical data provide the main inputs for decision-making in mineral exploration concerned with where to drill boreholes to find hidden ore bodies. In this chapter, the history of predictive geologic mapping with downward extrapolations from the Earth's surface was briefly reviewed. Special attention was paid to the first copper potential map for the Abitibi area on the Canadian Shield published in 1972 for copper-producing mines and prospects publicly available in 1968 using geological maps and geophysical data. During the next 10 years, this area was subjected to intensive prospecting for copper-containing mineral deposits permitting an evaluation of the original copper potential maps. Various statistical methods including logistic regression and the jackknife were used for assessing the uncertainties associated with predicting locations and amounts of copper in square cells of different sizes. In the final sections of this chapter, the relatively well-known method of weights of evidence (WofE) and the more recently developed method of local singularity analysis were briefly discussed with examples of the application using geologic maps and geochemical data.

Definition

Principal component analysis (PCA) is a statistical technique aimed to explore and reduce the dimensionality of a multivariate dataset. It is based on the key idea of finding a representation of the p -dimensional data through a smaller set of $k < p$ new variables, defined as linear combinations of the original variables. These are obtained as to explain at best the data variability. PCA was first introduced by Pearson (1901); nowadays its formulation has been developed for varied types of Euclidean data, including compositional data and functional data. Extensions to non-Euclidean data are available as well.

PCA as an Optimization Problem

It is given a dataset made of n observations of p variables, organized in a data matrix $\mathbb{X} = [x_{ij}]$ in $\mathbb{R}^{n \times p}$, whose columns are denoted by $\mathbf{x}_j = (x_{1j}, \dots, x_{nj})$. It is assumed that the variables have null sample mean ($\sum_{j=1}^n x_{ij} = 0$); otherwise, the data can be centered with respect to their sample mean prior to apply the PCA. The goal of the PCA is to define a new set of uncorrelated variables $\mathbf{z}_1, \dots, \mathbf{z}_p$, named *principal components* (PCs), linearly related with the original variables $\mathbf{x}_1, \dots, \mathbf{x}_p$, and suitable to effectively represent the data through a reduced representation based on $k < p$ PCs only – namely, through a new data matrix $\mathbb{Z} = [\mathbf{z}_1, \dots, \mathbf{z}_k]$ in $\mathbb{R}^{n \times k}$. The generic principal component $\mathbf{z}_{\cdot j} = (z_{1j}, \dots, z_{nj})^T$ is thus expressed as

$$z_{ij} = \xi_{j1}x_{i1} + \xi_{j2}x_{i2} + \dots + \xi_{jp}x_{ip}, \quad (1)$$

where the z_{ij} is named *principal component score* (or simply *score*) and represents the i -th observation of the j -th principal component, and the weights ξ_{ji} can be organized in a vector $\boldsymbol{\xi}_j = (\xi_{j1}, \dots, \xi_{jp})^T$, which is named *loading vector*. As exemplified in Fig. 1, the vector $\boldsymbol{\xi}_j$ identifies a direction in $\mathbb{R}^p$ along which the data are projected (obtaining the scores z_{ij}); hence, $\boldsymbol{\xi}_j$ is conventionally set to be a unit vector ($\|\boldsymbol{\xi}_j\|^2 = \sum_{\ell=1}^p \xi_{j\ell}^2 = 1$, with $\|\cdot\|$ the Euclidean norm). The PCA thus ultimately identifies k directions in $\mathbb{R}^p$, which together form a new representation space for the data.

Two requirements underlie the identification of the loading vectors $\boldsymbol{\xi}_j$: (1) the directions are set to be orthogonal to each other; and (2) the variability expressed by the data when projected along these directions is maximized. This leads to find the j -th loading vector as the solution of the optimization problem

$$\arg \min_{\boldsymbol{\xi}_j \in \mathbb{R}^p} \sum_{i=1}^n z_{ij}^2 \quad \text{subject to} \quad \|\boldsymbol{\xi}_j\| = 1, \quad (2)$$

$$\langle \boldsymbol{\xi}_j, \boldsymbol{\xi}_\ell \rangle = 0, \ell < j,$$

where the last orthogonality constraint $\langle \boldsymbol{\xi}_j, \boldsymbol{\xi}_\ell \rangle = 0$ (the symbol $\langle \cdot, \cdot \rangle$ denoting the Euclidean inner product) ensures the first requirement, and it is only imposed for $j > 1$ (i.e., not on the first PC). It can be proved that the optimization problem has a unique solution, which is found from the eigen-decomposition of the covariance matrix of the data $\mathbb{S} = \frac{1}{n-1} \mathbb{X}^T \mathbb{X}$, or, analogously, from the singular value decomposition of the data matrix $\mathbb{X}$ (see Johnson and Wichern (2002)). Here, the variances of the PCs, $\text{Var}(\mathbf{z}_{\cdot j})$, are found as the (ordered) eigenvalues of $\mathbb{S}$, while the loading vectors are the (ordered) eigenvectors of $\mathbb{S}$ (equivalent to the right singular vectors of $\mathbb{X}$).

A strong linear correlation among variables reflects on the presence of PCs associated with very low variability. In this case, the last PCs have sample variance approaching 0. In case of perfect linear relation among variables, only a set of $k < p$ PCs are associated to non-null variance (i.e., non-null eigenvalues of $\mathbb{S}$). In this case, the data matrix $\mathbb{X}$, as well as the covariance matrix $\mathbb{S}$, is not of full rank.

Principal Component Analysis, Fig. 1 Left: Finding a new system of coordinates through PCA to represent a set of bivariate data. Data are reported as gray symbols; directions of the PCs are depicted as straight lines; arrows indicate the loading vectors. The first PC is colored in blue, the second PC in red. Right: Interpretation of PCA as space of best

approximation, for a bivariate dataset (gray symbols). The direction of the first PC ($\text{span}\{\xi_1\}$) is depicted as a blue straight line; projections of the data as blue symbols; reconstruction errors are depicted as red segments. The MSE_1 is the sum of the squares of the lengths of the red segments

Alternative Geometrical Interpretation

The PCA can be alternatively interpreted as a method to build nested spaces of best approximation for the data. Indeed, one can prove that the linear space generated by the loading vectors of the first k PCs, $\text{span}\{\xi_1, \dots, \xi_k\}$, is the k -dimensional space of best approximation for the data, in the sense of minimizing the mean square error of approximation

$$MSE_k = \sum_{i=1}^n \left\| \mathbf{x}_i - \sum_{j=1}^k \langle \mathbf{x}_i, \xi_j \rangle \xi_j \right\|^2, \quad (3)$$

where $\mathbf{x}_i$ denotes the i -th row of the data matrix $\mathbb{X}$, and $\sum_{j=1}^k \langle \mathbf{x}_i, \xi_j \rangle \xi_j$ is the projection of $\mathbf{x}_i$ on $\text{span}\{\xi_1, \dots, \xi_k\}$.

In other terms, having at one's disposal k dimensions to reconstruct the dataset, the first k PCs offer the coordinate system minimizing the reconstruction error (in terms of Euclidean distance MSE_k). Note that, in general, the best reconstruction of dimension 0, in the sense of the MSE, is the sample mean $\bar{\mathbf{x}} = \frac{1}{n} \sum_{i=1}^n \mathbf{x}_i$. This alternative viewpoint to

PCA is often taken to generalize PCA to non-Euclidean spaces (e.g., in the principal geodesic analysis, Fletcher et al. (2004)).

Dimensionality Reduction

The PCA can be used to perform a dimensionality reduction of the dataset, by retaining only k out of the p PCs, and then using the reduced data matrix $\mathbb{Z} = [\mathbf{z}_1, \dots, \mathbf{z}_k]$ in $\mathbb{R}^{n,k}$ for further statistical processing. This is typically done by looking for an elbow in the *scree plot*, which depicts, as a function of k , the cumulative variance along the first k PCs, compared to the total variance of the data $\text{Var}_{tot} = \frac{1}{n} \sum_{j=1}^p \sum_{i=1}^n x_{ij}^2$

(an example is given in Fig. 2b). Note that, by construction, the variance of the j -th PCs, $\text{Var}(\mathbf{z}_j)$, is larger than the variances of successive PCs, i.e., $\text{Var}(\mathbf{z}_j) \geq \text{Var}(\mathbf{z}_\ell)$, $\ell > j$, and that $\text{Var}_{tot} = \sum_{j=1}^p \text{Var}(\mathbf{z}_j)$. A full representation of the total vari-

ance Var_{tot} can only be attained by retaining all the p PCs; however, in many cases, a set of $k < p$ PCs may be sufficient to explain a large amount of the data variability, particularly if the original variables are highly correlated. The number k of PCs to retain can then be set by thresholding the proportion of variance explained by the PCs, typical thresholds being 80%, 90%, or 95%.

Interpretation of the principal components is key for their use in practice. For this purpose, a useful representation is provided by the *biplot* (Gabriel 1971), which displays the

projection of the original variables in the Cartesian space defined by the first and second PCs (see Johnson and Wichern (2002)). An example of biplot corresponding to the PCA of a multivariate dataset with $p = 5$ is given in Fig. 2c.

The dimensionality reduction offered by PCA is useful to face the curse of dimensionality affecting data analyses as the number p of measured variables increases. In particular, if $p > n$ (a.k.a. *large p, small n problem*) several statistical techniques cannot be directly applied. In these cases, PCA can be used prior to further statistical processing, to single out a reduced data matrix $\mathbb{Z}$ of dimension $k \leq n$. These include, e.g., regression analysis in the presence of multicollinearity (principal component regression), where PCA is applied to the set of predictors. Other techniques which may benefit from dimensionality reduction to stabilize estimations or speed up computations are, in a spatial context, co-kriging and stochastic co-simulation (Chiles and Delfiner 2009).

Extensions

Several extensions of PCA to linear and nonlinear spaces are available. These include, among others, the principal component analysis for compositional datasets based on the Aitchison geometry (Pawlowsky-Glahn et al. 2015); the functional principal component analysis for functional data (e.g., curves or images) when these are embedded in Hilbert spaces (Ramsay and Silverman 2005); and the principal geodesic analysis for shape data (Fletcher et al. 2004).

Different representations can be used to perform dimensionality reduction of a multivariate dataset, while attaining slightly different maximization tasks. Among these, we mention independent component analysis (ICA; see Hyvriinen (2013)), which identifies independent variables; Fisher's canonical decomposition (see Johnson and Wichern (2002)), which identifies uncorrelated directions of maximum discrimination among groups in a classification setting; and multi-dimensional scaling (MDS; see Johnson and Wichern (2002)), which identifies a best approximation space in the sense of respecting the mutual distances among data points. PCA, however, unlike these alternatives, returns a *bi-orthogonal decomposition*, in the sense that the loading vectors are orthogonal, and the scores are uncorrelated, by virtue of the Karhunen-Loeve theorem. PCA is part of a broader class of statistical methods for the identification of latent factors, named factor analysis (see Johnson and Wichern (2002)).

Summary

Principal component analysis (PCA) allows one to reduce the dimensionality of a multivariate dataset, by finding directions of maximum variability of the data or, equivalently, nested

Principal Component Analysis, Fig. 2 Example of PCA of a multivariate dataset ($p = 5$). **(a)** Scatterplot of the original variables, showing significant correlation among variables. **(b)** Scree plot. Typical thresholds set at 80% and 90% of explain variability (red horizontal lines)

suggest to select $k = 1$. **(c)** Biplot. Data are reported in the coordinate system of the first and second PC; red arrows indicate the directions of the original variables

spaces of best approximation. The representation offered by PCA can be useful for further statistical processing, to face the curse of dimensionality affecting data analysis as the number p of measured variables increases. The geometrical perspective upon which the PCA is rooted enables its generalization to complex situations, pertaining constrained data (compositional, directional, spherical data) or infinite-dimensional data (functional, distributional data).

Probability Density Function

Abraão D. C. Nascimento
Universidade Federal de Pernambuco, Recife, Brazil

Synonyms

Density; Joint probability density function

Definition

This chapter aims to furnish the reader with knowledge on the probability density function (pdf). It is assumed as a prerequisite a course in elementary calculus and set theories.

Probability Measure

First consider the definition of two concepts: a σ -field of a set and a probability measure. Let Ω be the set of all outcomes formulated from a real random phenomenon, e.g., measurement of vegetation index from remote sensing radar (Maus et al. 2019) and description of intensities in synthetic aperture radar imagery (Ferreira and Nascimento 2020; Yue et al. 2021). A nonempty collection of subsets drawn from Ω , say $\mathcal{A}$, is said to be a σ -field of Ω if $\mathcal{A}$ satisfies two conditions (Hoel et al. 1973):

- (i) If $A \in \mathcal{A}$, then $A^c \in \mathcal{A}$.
- (ii) If $A_i \in \mathcal{A}$ for $i = 1, 2, \dots$, then $\bigcup_{i=1}^{\infty} A_i \in \mathcal{A}$ and $\bigcap_{i=1}^{\infty} A_i \in \mathcal{A}$, where A^c is the complement of a set A (i.e., the elements not in A) and $\cup$ and $\cap$ represent the union and intersection operations, respectively.
- (iii) A probability measure, say $\Pr(\cdot)$, on a σ -field of subsets $\mathcal{A}$ of a set Ω is a real-valued function having domain $\mathcal{A}$ satisfying the following properties (Hoel et al. 1973):
- (iv) $\Pr(\Omega) = 1$.
- (v) $\Pr(A) \geq 0$ for all $A \in \mathcal{A}$.
- (vi) If $\{A_n; n = 1, 2, \dots\}$ are mutually disjoint sets in $\mathcal{A}$, then

$$\Pr\left(\bigcup_{n=1}^{\infty} A_n\right) = \sum_{i=1}^{\infty} \Pr(A_n).$$

From the previous system, various properties can be derived, e.g.:

- (vii) (Boole's inequality) If $\{A_i; i = 1, 2, \dots, n\}$ are any sets, then

$$\Pr\left(\bigcup_{i=1}^n A_i\right) \leq \sum_{i=1}^n \Pr(A_i).$$

- (viii) $\Pr(A_1 \cap A_2 \cap \dots \cap A_n) = \Pr(A_1)\Pr(A_2|A_1)\Pr(A_3|A_1 \cap A_2) \dots \times \Pr(A_n|A_1 \cap \dots \cap A_{n-1})$,

$\forall A_1, \dots, A_n \in \mathcal{A}$, and $\forall n = 1, 2, \dots$, where $\Pr(A_i|B) := \Pr(A_i \cap B)/\Pr(B)$ for $\Pr(B) > 0$ is the conditional probability, one of the most important concepts of probability theory. From the latter, one can define the notion of *independence of two sets* that says: two sets A and $B \in \mathcal{A}$ are independent if $\Pr(A \cap B) = \Pr(A)\Pr(B)$.

- (ix) (Bayes' formula) Let $\{A_i; i = 1, 2, \dots\}$ be a sequence of events that represent a partition of Ω , then

$$\Pr(A_i|B) = \frac{\Pr(A_i)\Pr(B|A_i)}{\sum_{j=1}^{\infty} \Pr(A_j)\Pr(B|A_j)}, \quad \forall B \in \mathcal{A}.$$

From on now, a *probability space*, denoted by $(\Omega, \mathcal{A}, \Pr)$, is a system that approaches a set of events Ω , a σ -field of subsets $\mathcal{A}$, and a probability measure $\Pr : \mathcal{A} \mapsto (0, 1)$.

Random Variables and Vectors

A mapping $X : \Omega \mapsto \mathcal{X} \subset \mathbb{R}$ is said to be a *random variable* (RV) if:

- (x) It is a real-valued function defined on a sample space on a collection of subsets having defined probability.
 (xi) For every Borel set $B \subset \mathbb{R}$, $\{w \in \Omega : X(w) \in B\} \in \mathcal{A}$, where Borel set represents any set in a topological space which is obtained from union, intersection, and complement operations of open or closed sets. Such sets are crucial in the measure theory because any measure formulated on the open or closed sets of a pre-specified space needs to be defined on all Borel sets of such space.

As an extension of X , $\mathbf{X} = (X_1, \dots, X_p)^T : \Omega \mapsto \mathcal{X} \subset \mathbb{R}^p$ is a random vector if X_i is random variable for $i = 1, \dots, p$, where $(\cdot)^T$ is the transposition operator.

In practical terms, an RV represents a numerical value defined from the outcome on the random experiment. Mathematically, it requires $\Pr(X \leq x)$ for all $x \in \mathbb{R}$ to be well-defined or, equivalently, $\{w \in \Omega : X(w) \leq x\}$ belongs to $\mathcal{A}$. Thus, it is necessary to define the cumulative distribution function (cdf) of an RV. Let X be an RV defined on $(\Omega, \mathcal{A}, \Pr)$, its cdf, say $F_X : \mathcal{X} \mapsto [0, 1]$, is given by

$$F_X(x) = \Pr(X \leq x).$$

The cdf is nondecreasing and continuous from the right, satisfying $\lim_{x \rightarrow -\infty} F(x) = 0$ and $\lim_{x \rightarrow \infty} F(x) = 1$. The cdf plays a crucial role to compute probability of events, e.g., $\Pr(a < X \leq b) = F_X(b) - F_X(a)$ for $a \leq b$. For random vectors, the joint cumulative distribution function (jcdf) of $\mathbf{X}$, say $F_X : \mathcal{X} \mapsto [0, 1]$, is given by

$$F_X(x_1, \dots, x_p) = \Pr(X_1 \leq x_1, \dots, X_p \leq x_p).$$

The jcdf is non-decreasing for x_i (for all $i = 1, \dots, p$) in $(x_1, \dots, x_{i-1}, x_i, \dots, x_p)$, i.e., if $x_{i_1} < x_{i_2}$, then

$$F_X(x_1, \dots, x_{i_m}, \dots, x_p) \leq F_X(x_1, \dots, x_{i_2}, \dots, x_p).$$

The jcdf is continuous from the right for x_i , i.e., if $x_{i_1} \downarrow x_{i_m}$ for $m \rightarrow \infty$,

$$F_X(x_1, \dots, x_{i_m}, \dots, x_p) \downarrow F_X(x_1, \dots, x_{i_1}, \dots, x_p) \text{ for}$$

$$m \rightarrow \infty.$$

Further

$$\lim_{\forall i, x_i \rightarrow -\infty} F_X(x_1, \dots, x_i, \dots, x_p) = 0$$

$$\text{and } \lim_{\forall i, x_i \rightarrow \infty} F_X(x_1, \dots, x_i, \dots, x_p) = 1.$$

Probability Density Function

The nature of the under study phenomenon determines the kind of variable to be used, discrete, or continuous. Let X be a real-valued RV on $(\Omega, \mathcal{A}, \Pr)$, then

- (xii) X is a discrete RV if it has as both domain Ω and range $\mathcal{X}$ a finite or countably infinite subset $\{x_1, x_2, \dots\} \subset \mathbb{R}$ such that $\{w \in \Omega : X(w) = x_i\} \in \mathcal{A}$ for all $i = 1, 2, \dots$.
 (xiii) X is a continuous RV if it has $\mathcal{X} \subset \mathbb{R}$ such that $\Pr(\{w \in \Omega : X(w) = x\}) = 0$ for $-\infty < x < \infty$.

From now on, this discussion will focus on the continuous case.

The cdf of a continuous RV is often defined in terms of its probability density function (pdf). The pdf of X is a nonnegative function, say $f_X : \mathcal{X} \mapsto [0, \infty)$, such that

$$\int_{-\infty}^{\infty} f_X(x) dx = \int_{\mathcal{X}} f_X(x) dx = 1.$$

Note that $F_X(x)$ and $\Pr(X \in B)$ can be rewritten as

$$F_X(x) = \int_{-\infty}^x f_X(t) dt \text{ and } \Pr(X \in B) = \int_B f_X(t) dt,$$

respectively. The pdf can also be deduced from $f_X(x) = dF_X(x)/dx$. For random vectors, the joint probability density function (jpdf) of $\mathbf{X}$ is a nonnegative function, say $f_X : \mathcal{X} \mapsto [0, \infty)$, such that

$$\int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} f_X(\mathbf{t}) dt_1 \dots dt_p = \int_{\mathcal{X}} f_X(\mathbf{t}) dt_1 \dots dt_p.$$

Note that $F_X(x)$ and $\Pr(\mathbf{X} \in \mathbf{B})$ for $\mathbf{B} \subset \mathcal{X}$ can be explicated as

$$F_X(\mathbf{x}) = \int_{-\infty}^{x_1} \cdots \int_{-\infty}^{x_p} f_X(\mathbf{t}) dt_1 \cdots dt_p \quad \text{and}$$

$$\Pr(X \in \mathbf{B}) = \int \cdots \int_{\mathbf{B}} f_X(\mathbf{t}) dt_1 \cdots dt_p.$$

Analogous to the univariate counterpart, the jpdf arises from $f_X(\mathbf{x}) = d^p F_X(\mathbf{x})/dx_1 \cdots dx_p$.

Some Statistical and Computational Essays

Now we are in a position of illustrating the pdf shape of some univariate and multivariate distributions. Hundreds of continuous univariate distributions have been extensively used for modeling phenomena in various areas of science (cf. Cordeiro et al. 2020). The most employed one is the normal (or Gaussian) distribution, having its univariate version support in $\mathbb{R}$ and as parameters the mean $\mu \in \mathbb{R}$ and standard deviate $\sigma > 0$ and its p variate counterpart domain in $\mathbb{R}^p$ and parameters, the mean vector $\boldsymbol{\mu} \in \mathbb{R}^p$ and covariance matrix $\boldsymbol{\Sigma} \succcurlyeq \mathbf{0}$, where $\succcurlyeq \mathbf{0}$ represents the nonnegative definite condition. Their pdfs are presented in Table 1. This case is denoted as $X \sim N_p(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ for the multivariate case and $X \sim N(\mu, \sigma^2)$ for the univariate. An alternative distribution to the N_p law is the t -student distribution. Similar to the normal, this law is symmetric having pdf with heavy tails driven by the parameter ν called degree of freedom (df), and it is denoted as $X \sim t_\nu$. The smaller the parameter ν is, the heavier the tail is. Figure 1a illustrates the relation between $N(\mu, \sigma^2)$ and t_ν distributions. Note that the latter tends to the former when increasing ν and the t_2 law has the most heavy tail. From the relation between these two distributions, the most used t and Hotelling's T^2 tests for the null hypotheses $\mathcal{H}_{01}: \mu = [\mu_0 \in \mathbb{R}]$ and $\mathcal{H}_{02}: \boldsymbol{\mu} = [\boldsymbol{\mu}_0 \in \mathbb{R}^p]$ arise from, respectively:

- (Univariate case: the t test) Let $X_1, \dots, X_n$ be an independent and identically distributed (iid) sample of size n

drawn from $X \sim N(\mu, \sigma^2)$; then the appropriate test statistic (called t statistic) for $\mathcal{H}_{01}$ is

$$S_t = \frac{\bar{X} - \mu}{S/\sqrt{n}} \sim \mathcal{H}_{01} t_{n-1} \quad \text{or} \quad S_t = \frac{\bar{X} - \mu_0}{S/\sqrt{n}} \sim t_{n-1},$$

where $\bar{X} = n^{-1} \sum_{i=1}^n X_i$ is the sample mean, $S^2 = (n-1)^{-1} \sum_{i=1}^n (X_i - \bar{X})^2$ is the sample variance, and “ $\sim \mathcal{H}_{01}$ ” represents a variable distributed as a distribution law under the hypothesis $\mathcal{H}_{01}$. As a decision rule, we reject $\mathcal{H}_{01}$ when $|S_t|$ is large.

- (Multivariate case: the Hotelling's T^2 test) Let $X_1, \dots, X_n$ be an iid sample of size n obtained from $X \sim N_p(\boldsymbol{\mu}, \boldsymbol{\Sigma})$; then the appropriate test statistic for $\mathcal{H}_{02}$ (named Hotelling's T^2 statistic) is

$$T^2 = n(\bar{X} - \boldsymbol{\mu}_0)^T \mathbf{S}^{-1} (\bar{X} - \boldsymbol{\mu}_0) \sim \frac{(n-1)p}{(n-p)} \mathcal{F}_{p, n-p},$$

where $\bar{X} = n^{-1} \sum_{i=1}^n X_i$, $\mathbf{S} = (n-1)^{-1} \sum_{i=1}^n (X_i - \bar{X})(X_i - \bar{X})^T$ and $\mathcal{F}_{p, n-p}$ represents the F-Snedecor with degree of freedom p and $n-p$ (which is defined as the ratio of two independent random variables following the chi-square distribution divided by their dfs, termed χ_k^2 in Table 1). Thus, if T^2 is too large, we have evidence to reject H_{02} .

Emery (2008) showed that t and Hotelling's T^2 tests are crucial to check the fit quality in geoscience applications. The N_p distribution (analogous to the t -student law) is symmetric. Figure 2a displays two groups of level curves for this law. To extend the N_p distribution, Azzalini and Valle (1996) pioneered the skew-normal (SN) distribution having pdf given in Table 1. Figure 2b illustrates that the SN level curves can describe the skewness multivariate database, while Fig. 1b confirms this property for a univariate perspective.

Probability Density Function, Table 1 Some pdfs of random variables and vectors. $\phi(\cdot)$ and $\Phi(\cdot)$ are the standard normal pdf and cdf. $\phi_p(\cdot)$ is the p -variate standard normal pdf. $|\cdot|$ and $(\cdot)^{-1}$ are the matrix determinant and inverse operations

Probability Density Function, Fig. 1 Curves for normal, t -student, and SN pdfs

Probability Density Function, Fig. 2 Curves for multivariate normal and SN jpdfs

Finally, one of the most used positive distributions is the gamma law that has two parameters: one of shape, $\alpha > 0$, and another scale, $\beta > 0$. This case is denoted by $\Gamma(\alpha, \beta)$ and its pdf is presented in Table 1. The Γ distribution is known as the mother law for describing the speckle noise in synthetic aperture radar system (Ferreira and Nascimento 2020). Mathai and Moschopoulos (1992) proposed a multivariate gamma version having jpdf given in Table 1.

Probabilistic Approach in Geoscience Problems

Many geoscience applications can be understood as random experiments, e.g., on resource characterization (Ma 2019) and measurements of features obtained from remote sensing data (Maus et al. 2019) or SAR imagery (Yue et al. 2021). Thus, it is required to use a probability approach and pdf to describe

geoscience data. Particularly, Ma (2009) showed evidence that the previous axioms iii, iv, and v are crucial to deal with depositional facies analysis, while (Tolosana-Delgado and van den Boogaart 2013) addressed the importance of them to analyze mineral and geochemical elements. Finally, Ma (2019) have pointed out that the use of (a) probability dilemmas and the conditional probability concept and (b) pdfs and jpdfs in the probabilistic mixture are vital to understanding the physical conditions and statistical properties of geoscience phenomena.

Conclusion

In this chapter, we have presented the main concepts for understanding the probability density function (pdf). Some particular jpdfs and pdfs were approached and related to t and

Hotelling's T^2 statistical tests. The latter are important tools in geoscience applications. In summary, the probability approach consists of a base to deal with several geoscience problems, like resource evaluation and mapping by remote sensing sources.

Proximity Regression

Jaya Sreevalsan-Nair
Graphics-Visualization-Computing Lab, International
Institute of Information Technology Bangalore, Electronic
City, Bangalore, Karnataka, India

Definition

Geological features include mineral deposits, intrusions, faults, etc. It is known that the distance to the geological feature, i.e., distance to mineralization, is influenced by several geochemical variables or entities. These variables include the trace elements and the major oxides. The goal is to identify multi-element signatures (Bonham-Carter and Grunsky 2018) in the proximity to the geological features, and locate other regions with similar signatures. To

accomplish such data analysis, linear regression models using *proximity* are used.

Proximity is defined as a function related to distance, just as similarity, where proximity is inversely proportional to distance (Bonham-Carter and Grunsky 2018). The rate of decay of proximity with distance can be considered to be a constant. Thus, by integrating the rate value, we get proximity to be an exponential function of distance. While this can be used for modeling proximity, say at half distance, it can also be predicted using known values of geochemical variables. Such a prediction is done using a linear regression model. Thus, *proximity regression* is the linear regression model of predicting proximity, as the response or dependent variable, using the geochemical variables as the predictors or the independent variables (Bonham-Carter and Grunsky 2018). For proximity Y , expressed as a real value in $[0,1]$, the corresponding distance from feature Z ranges from infinity to zero. Using constant function, $\frac{dY}{dZ} = -\alpha$, which upon integration gives: $Y(Z) = Y(0)e^{-\alpha Z}$.

At half distance $Z_{0.5}$, $\frac{Y(Z_{0.5})}{Y(0)} = 0.5$, thus $\alpha = \frac{-\ln 0.5}{Z_{0.5}} \Rightarrow Y(Z) = \exp\left(\frac{\ln 0.5}{Z_{0.5}} \cdot Z\right)$.

Overview

A dispersion halo is a physical phenomenon that is observed in the country rocks, where a region around a mineral deposit exhibits higher metal values compared to those of the deposit and considerably higher than background values. Usually geochemical sampling and testing are used to delineate the dispersion halo. For computations, proximity is one such measure used for modeling the dispersion halo. While distance to the geological feature is the direct observation, proximity is preferred over distance to be regressed on the geochemical variables for modeling the dispersion halo around a mineral deposit. This is because of the decay of the halo following an exponential function or a power law. Hence, using a measure, such as proximity, that is modeled as a similar function of distance in a linear regression model, improves its prediction. Overall, proximity is modeled as an inversely proportional function of distance (Bonham-Carter and Grunsky 2018).

For using proximity regression, proximity values in close range to the selected feature are used. For dependent variables, the centered logratio (CLR) transformed values of the element values are used in the form of a matrix X of size $m \times n$ for m geochemical variables and n samples or observations. Thus, the column vector of response variables of size n , used in a linear regression model, is given by $Y = X\beta + \varepsilon$, where β is the coefficient (column) vector of size n , and ε is the error (column) vector of size n . This overdetermined equation, as

$m \leq n$, is solved using the least squares method or the conjugate gradient method.

For studying geochemistry of soil samples, compositional data analysis is routinely used, owing to the constant sum constraint (Aitchison 1982). A linear transformation of the Aitchison geometry or simplex, which is the representation of the data points in the compositional data, is used to convert the data to real space. The centered logratio (CLR) is one such linear transformation that is effectively used for the geochemical variables, to avoid the closure problem (Bonham-Carter and Grunsky 2018). The closure problem arises from the standard multivariate analysis to compositional data, where there is a negative bias in the product-moment correlation between the constituents of a geochemical composition (Pawlowsky-Glahn et al. 2007). CLR transformation is also used in applications involving principal component analysis for dimensionality reduction (Pawlowsky-Glahn et al. 2007). CLR transformation involves dividing samples by the geometric mean of its values, and then using its logarithm values. While all components are treated symmetrically in CLR transformation, the transformed data may exhibit collinearity, which is not applicable for methods using full rank data matrices (Filzmoser et al. 2009). In cases of collinearity in the CLR data, the isometric logratio transformation (ILR) is alternatively used (Egozcue et al. 2003; Filzmoser et al. 2009).

Applications

Proximity regression has been applied in the study of litho-geochemistry of volcanic rocks in the Ben Nevis township, Ontario, Canada. Usually auto- and cross-correlations of the geochemical variables are useful in computations of spatial factors for factor analysis methods used for distinguishing litho-geochemical trends from geological processes (Grunsky and Agterberg 1988). It is observed that the anisotropically distributed variables are delineated better than isotropically distributed ones, when using the spatial factor maps. Such a multivariate analysis helps in identifying the dispersion halo that reflects mineralization. Expanding this and other similar works to identifying specific mineral occurrences in Canagau Mines deposit and Croxall property in the Abitibi Greenstone Belt, proximity regression has been used (Bonham-Carter and Grunsky 2018). This method also predicts the Croxall property using the Canagau Mines deposit, using 26 geochemical variables, and 278 samples within 3 km of Canagau Mines

deposit, for training. In addition to identifying these regions as “bulls-eye,” the method has enabled in identifying the predictors or independent variables that identify Croxall property based on the training on the Canagau Mines deposit.

Future Scope

Prospectivity mapping can be considered to be an organic successor to proximity regression-based methods. This can be applied by constructing the proximity measure to the nearest mineral deposit. The problem can be then reframed as predicting the proximity to the nearest mineral occurrence, instead of the occurrence of a mineral deposit (Bonham-Carter and Grunsky 2018).

Different from other spatial regression methods, where proximity and its analogues are used as independent variables, proximity regression is one of the methods where proximity is the response variable. The methodology for prediction can itself be improved through machine learning using neural networks. Alternative to linear regression, logistic regression can be used to strictly constrain the range of proximity to (0,1) (Bonham-Carter and Grunsky 2018). ILR can also be considered as an alternative to CLR for transforming the independent variables (Filzmoser et al. 2009).

Overall, proximity regression is a multivariate predictive method used in multivariate compositional data.

Q

Q-Mode Factor Analysis

Norman MacLeod

Department of Earth Sciences and Engineering, Nanjing University, Nanjing, Jiangsu, China

Definition

Q-Mode Factor Analysis – a statistical modelling procedure whose purpose is to find a small set of latent linear variables that estimate the influence of the factors controlling the structure of case similarities/dissimilarities in a multivariate dataset and are optimized to preserve as much of the inter-case similarity or dissimilarity structure as appropriate given an estimate of the number of causal influences.

Introduction

Whereas a linear, multivariate data-analysis procedure whose purpose was to summarize the covariance/correlation structure among a set of variables (*R*-mode) was first introduced by Karl Pearson (1901), the development of linear procedures whose purpose was to summarize the similarity/dissimilarity structure among sets of cases (e.g., objects, samples or events) (*Q*-mode) is of more recent vintage. This type of multivariate data analysis was introduced into the earth-science literature by John Imbrie (1963) based on previous applications in the fields of psychology and biology. Both principal component analysis (PCA) and component-based, *R*-mode factor analysis (FA) can be used to create mathematical ordination spaces into which cases described by the variables can be projected. Cases that plot close to each other in such spaces can be regarded as having similar variable values and cases that plot at some distance from others can be regarded as having different variable values. But in *R*-mode analyses the spaces created by these methods are referenced to the structure of

covariance or correlation relations among the variables, not similarity relations among the cases themselves. The *Q*-mode methods of principal coordinates analysis (PCoord) and component-based *Q*-mode factor analysis (QFA) were created to redress this deficiency.

Estimating Similarity

Just as the core of the PCA and FA lies in the manner in which pairwise structural relations among variables are portrayed, the core of QFA lies in the manner in which pairwise structural relations among cases are portrayed. But while in *R*-mode methods this usually comes down to a choice between two quite distinct alternatives – covariance or correlation – in *Q*-mode methods a wide variety of similarity and dissimilarity indices are available. Moreover, across the earth sciences it is often the case that variable values are reported as proportions or percentages, a practice that adds complexity to QFA calculations (Table 1).

The similarity coefficients or indices used in QFA can be classified into several types: binary association indices, distance indices, and proportional similarity indices. Binary association indices, such as the coefficients of Jaccard, Dice, Simpson, and Otsuka (Table 1; see Cheetham and Hazel 2012 for a review), are used exclusively for presence-absence datasets and have been applied most extensively in the context of *Q*-mode cluster analysis. They do, however, produce “similarity” matrices than can be operated on by any number of multivariate data-analysis procedures, including QFA. Owing to the count of either mutual presences, or mutual absences, appearing in the numerators of these ratios, the selection of particular binary association indices will focus the analysis on the structure of similarity associations, dissimilarity associations, or some combination of both (Table 2).

Distance-based indices are the most readily understandable family of *Q*-mode similarity coefficients because they

five *Q*-mode distance
(dissimilarity)
coefficients

Euclidean Distance	Squared Euclidean Distance
$d_{ij} = \sqrt{\sum_{k=1}^p (x_{i,k} - x_{j,k})^2}$	$d_{ij}^2 = \sum_{k=1}^p (x_{i,k} - x_{j,k})^2$
Manhattan Distance	Mahalanobis Distance
$D_{ij} = \vec{x}_i - \vec{x}_j $	$D_{ij} = (\vec{x}_i - \vec{x}_j)^T S^{-1} (\vec{x}_i - \vec{x}_j)$
Gower Distance	
$g_{ij} = \frac{\sum_{k=1}^p x_{i,k} - x_{j,k} / range_k}{p}$	

x_i = The i^{th} case. x_j = The j^{th} case. p = no. of variables, S = covariance/correlation matrix for the p variables

represent case similarity and difference as a spatial construct. Euclidean, squared Euclidean, Manhattan, and Mahalanobis distances (Table 2) are all examples of distance indices that can be used to express the structure of relations between cases by summarizing pairwise differences across all variables. Because the trace of a pairwise, n by n distance matrix will always be occupied by zeros (since the distance between any object, sample or event with itself = 0.0), distance-based indices are often said to record “dissimilarity”.

Distance indices are applied typically to sets of interval or ratio data values and in situations where it is desirable to retain the magnitude or range of each variables’ values in the analysis. However, if a dataset contains a broad mixture of variable types, or if the data analyst wishes to minimize the influence of different variables’ numerical ranges, Gower’s distance (Gower 1971) may be used. When using Gower’s distance it should be kept in mind that atypical variable values can inflate a variable’s range and so have a disproportionate effect on the resulting pairwise similarity estimate. Ideally, outliers should be removed prior to the calculation of Gower distances and the number of different variable types balanced insofar as possible.

Weights may also be employed to control the relative influence of different variables on the overall measure of similarity though, as pointed out by Gower (1971), justification of an appropriate set of weights in the context of particular investigations is usually quite difficult. Here, the temptation to devise a weighting scheme that will either produce a particular ordination or speed calculations will be ever-present. Such temptations should be resisted.

The final type of similarity index often employed in QFA is Imbrie and Purdy’s (1962) index of proportional similarity.

$$\cos \theta_{ij} = \frac{\sum_{k=1}^p x_{i,k} x_{j,k}}{\sqrt{\sum_{k=1}^p x_{i,k}^2 \sum_{k=1}^p x_{j,k}^2}} \quad (1)$$

In this equation x_i is the i^{th} case; x_j = is the j^{th} case; and p = is the no. of variables. This is by far the similarity index most commonly employed in QFA and often constitutes the default index in public-domain and commercial statistics and data-analysis software packages. The proportional similarity index is often referred to as the “cosine θ ” index because it conceptualizes cases as vectors in the variable space and represents similarity as the angular difference between all pairwise combinations of case vectors, taking no account of these vectors’ lengths. Accordingly, the cosine θ index is a bounded index, constrained to vary between 0 and 1. The cosine θ , or proportional similarity, index is also a true similarity index insofar the trace of the resulting matrix is occupied by 1 s. If the variables used to compute the cosine θ index are standardized prior to similarity estimation the resulting values will be identical to those estimated from a calculation of the “correlation” across variables.

The Method

Once a similarity/distance matrix has been obtained the QFA procedure conforms closely to that of FA. The linear model used in QFA derives from Spearman’s (1904) original formulation and separates the observed n by n similarity or distance structure among cases, calculated across all variables, into a set of a priori designated generalized factors with a residual, specific factor (e) associated with each of the n cases.

$$\begin{aligned}
X_1 &= a_{1,1}F_1 + a_{1,2}F_2 \cdots + a_{1,m}F_m + e_1 \\
X_2 &= a_{2,1}F_1 + a_{2,2}F_2 \cdots + a_{2,m}F_m + e_2 \\
X_3 &= a_{3,1}F_1 + a_{3,2}F_2 \cdots + a_{3,m}F_m + e_3 \\
&\vdots \\
X_j &= a_{j,1}F_1 + a_{j,2}F_2 \cdots + a_{j,m}F_m + e_j
\end{aligned} \quad (2)$$

In this expression a_i is a standardized score the i^{th} case, F is the “factor” value for that case across all measured or observed variables, and e_i is the part of the distance or similarity not accounted for by the factor structure. Q -mode factor analysis attempts to find a set of m linear factors (F , where $m < p$) that underly the sample’s similarity or distance structure and, hopefully, provide a good estimate of the similarity/distance structure of the larger population from which the sample was drawn.

Choosing and Extracting the Factors

In a manner analogous to its R -mode counterpart, QFA begins with a principal coordinate analysis of a properly selected basis matrix whose structure reflects those aspects of between-case similarity, distance or association most appropriate for the investigation at hand. The decision of which similarity, distance or association index to use is not a trivial one as it will influence all aspects of the subsequent analysis. In addition, the number of factors the investigator wishes to construct their model around also needs to be specified at the outset of analysis. The guidance for factor number selection offered in the presentation of R -mode FA can also be applied to QFA. As always, there is no substitute for having a detailed understanding of the system being modeled. If there is uncertainty regarding the number of factors controlling the dataset’s distance/similarity structure, QFA may proceed, but its results should be interpreted with caution.

Like R -mode FA, QFA scales the loadings of the retained principal coordinates by their eigenvalues, according to the following expression.

$$a_{i,m} = \sqrt[2]{\lambda_m} b_{i,m} \quad (3)$$

Here, λ_m is the eigenvalue associated with the m^{th} principal coordinate with m being set to the number of retained factors and b the eigenvector loading of the i^{th} case on the m^{th} principal coordinate (= factor). This scaling, along with the reduction in the number of factors being considered, represents a basic difference between PCoord and QFA.

Next, the “communality” values of the scaled factors are calculated as the sum of squares of the factor loading values

(a) across all factors. This summarizes the proportion of similarity, distance or association provided by each case to each factor. The quantity ‘1- the sum of communality values for each case, then, expresses the proportion of the case’s distance, similarity, or association structure attributable to the error term (e) of the factor model. If the correct number of factors has been chosen, all the summed, squared factor values should exhibit a high communality for each case with a small residual error.

Once the QFA factor equations have been determined, the factor loading values constitute the positions of objects, samples or events projected into the space formed from the eigenvalue-scaled orthogonal factors. These projection scores ($\hat{X}$) may then be tabulated, plotted, inspected and interpreted in the manner normal for PCoord ordinations. Table 3 and Fig. 1 compare and contrast results of a PCoord and two-factor QFA solution for the trilobite data listed in MacLeod (2006).

Note that, despite the cosine θ basis for this analysis being a square 20 x 20 matrix, only three principal coordinates can be extracted from this small, demonstration dataset. This limitation stems from the fact that the data from which the similarity matrix was calculated included only three variables: body length, glabella length and glabella width. For this simple dataset both the first principal component and first factor would be interpreted as being consistent with generalized size variation owing to their uniformly positive loading coefficients. Similarly, for both analyses the second component/factor would be interpreted as reflecting localized shape variation owing to the contrast between signs among the different taxa.

Figure 1 illustrates the distribution of these trilobite body shapes in the ordination space formed by the first two principal coordinate axes and the two retained factor axes. While the relative positions of the projected data points are also similar, and discontinuities in the gross form distributions are evident in both plots, the scaling of the PCoord and FA axes differ reflecting the additional eigenvalue-based scaling calculation that is part of component-based QFA. Irrespective of this correspondence, an important change has taken place in the ability of the QFA vectors to represent the structure of the original cosine θ similarity matrix (Table 4).

From these results it is evident that the two-factor QFA has been much more successful in reproducing the entire structure of the original cosine θ similarity matrix than principal coordinate analysis. If all 20 principal coordinates had been used in these calculations the trace of the original similarity matrix would be reproduced exactly, but none of the off-diagonal elements. This simple demonstration illustrates how the eigenvalue-scaling operation, that stands at the core of both FA and QFA, render these approaches to data analysis more

Q-Mode Factor Analysis, Fig. 1 Ordination spaces formed by the first two principal coordinates (A) and a two-factor extraction (B) from the three-variable trilobite dataset. Note the similarity of these results in

terms of the relative positions of forms projected into the PCoord and factor spaces and the difference in terms of the axis scales

information-rich than their PCA and PCoord counterparts, especially if a dramatic reduction in causal-factor dimensionality is required. The validity of applying either the FA or QFA models to a dataset is predicated, however, on the dataset exhibiting a factor-based variation/similarity structure.

Aside from the use of different indices to quantify the structure of pairwise relations among cases, QFA also differs

from R-mode FA in a number of other, more subtle ways. For example, it is standard practice to mean center each variable prior to analysis in PCA and FA so the ordination space created as a result of those procedures will be centered on the origin of the coordinate system within which the ordination results will be displayed. This operation is typically not performed in QFA (or PCoord) for either the set of variables

or the set of cases. In this way, the ordination actually expresses the orientation of eigenvectors all of whose tails emanate from the coordinate system origin, irrespective of whether the shafts or bodies of the eigenvectors are drawn in the Q -mode ordination space plots. It would also make little

sense to mean center the case rows across a set of variables of very different types and magnitude ranges.

When QFA ordinations are examined the loadings (= ordination scores) on the first factor (F1) will often all exhibit comparably high positive values. This is usually is a

reflection of the “size” or combined magnitudes of all the variables included in the analysis. Since there often seems to be little difference among the cases along F1 it is often regarded as an irrelevant or “nuisance” factor, especially when compared to the oftentimes more informative distinctions between cases revealed in the plots of higher-level QFA ordination spaces. Nonetheless, as uniformly high correlations among variables are not characteristic of all earth science datasets, it is always a good idea to inspect the F1 vs F2 and (if necessary) F1 vs F3 ordination plots to determine whether any useful insight can be gained into the structure of between-case similarity/distance relations from an interpretation of F1.

In some instances the variables being analyzed might be expressed as either compositional proportions or percentages such that the sum of each row is constrained to add up to 1.0 or 100.0, respectively. Such datasets are said to have been artificially “closed”. In such cases, application of a centered log-ratio transformation prior to analysis is usually recommended in order to mitigate the effects of the closure constraint.

Factor Rotation

As with FA, QFA factor axes may be rotated relative to the variable axes in order to improve their interpretability. Axis rotation is less commonly applied in QFA because the emphasis is often on identifying the structure of similarity relations

among cases rather than interpretation of the factors in terms of the original variables. Nonetheless, such interpretations are possible and factor-axis rotations often make this interpretation easier. Operationally this amounts to adjusting the set of factor loadings, rigidly in a geometric sense, until all variables exhibit loadings at or as close to 0.0 or ± 1.0 across all factors as possible.

Neuhaus and Wrigley’s (1954) quartimax, and Kaiser’s (1958) varimax orthogonal axis-rotation procedures can be used to perform this operation. If even more simplification is desired the constraint of the factor axes maintaining orthogonal relations can be relaxed using procedures such as Carroll’s (1953) quartimin or Imbrie’s (1963) oblique axis rotation, in which case the factor axes will coincide with the orientation of the extreme variable vectors. Figure 2 illustrates the unrotated and varimax-rotated solutions for the example trilobite dataset.

Conclusion

Q-mode factor analysis is often used to array cases along a spectrum defined by opposing case extrema. In some instances the purpose is to identify these extreme end-members while, in others, it is to gauge which of these spectral end-members particular cases are closest (= most similar) to. Such analyses can also be accomplished, to some extent, by Q-mode cluster analysis. However, in most

Q-Mode Factor Analysis, Fig. 2 Original (a) and rotated (b) variable-axis orientations with respect to the fixed, orthogonal factor axes for the three-variable trilobite data. The rotation of these variables is centered on

Factor 1 owing to their high mutual correlations (reflected in the high Factor 1 eigenvalue, see Table 3). More complex datasets will typically exhibit larger variable-vector rotations

cases cluster analysis represents the structure of between-case similarity relations as a hierarchy despite the fact that the generative processes that give rise to between-case structural relations might not be organized hierarchically. For systems in which similarity-distance relations are known, or suspected, not to be structured hierarchically, QFA may be the more appropriate conceptual model to employ in addition to one that will minimize the distortions that often accompany attempts to portray non-hierarchically structured data using hierarchical models.

Q-mode factor analysis has proven especially attractive to geochemists, mineralogists petrologists, hydrologists, paleo-ecologists, and biostratigraphers who often deal with compositional data and find themselves in need of a procedure to non-hierarchically define both end-members and gradient orderings of cases in which a number of influences are mixed in varying proportions. In perhaps one of the more scientifically significant applications of the method, Imbrie and Kipp (1971) employed QFA to develop a sets of linear transfer functions whereby sea surface temperatures for ancient ocean basins could be inferred from the relative abundances of Cenozoic planktonic foraminifer species. Sepkoski (1981) also used QFA to summarize the diversity history marine life across the Phanerozoic and used the results generated through its application to recognize the three great evolutionary faunas that, together, constitute fundamental macroevolutionary historio-structural units of life on Earth. These are but two prominent examples of QFAs potential for

making important data analysis-based advances in the study of earth history.

Quality Assurance

N. Caciagli

Metals Exploration, BHP Ltd, Toronto, ON, Canada
Barrick Gold Corp, Toronto, ON, USA

Synonyms

QAQC; Quality Control; Quality Management; Quality Systems

Definition

Quality assurance is the act of giving confidence or the state of being certain that a product or service is fit for use or conforms to specifications.

The ISO 9000 standard, clause 3.2.11 defines Quality Assurance as: “A part of quality management focused on providing confidence that quality requirements will be fulfilled”. (ref ISO 9000)

Quality assurance (QA) encompasses all the planned and systematic activities implemented to provide confidence that a product or service will fulfill requirements for quality. Quality control (QC) typically refers to the operational techniques and activities used to fulfill requirements for quality (ASQ/ANSI 2008). Often “quality assurance” and “quality control” are used interchangeably, referring to all the actions performed to ensure the quality of a product, service, or process.

Why QAQC

Quality assurance can be viewed as proactive and process oriented and is focused on the actions that produce the product or ensure the conditions a service must provide. In the geosciences, quality assurance considers the requirements of the data and often deals with the selection of appropriate analytical methods, standards to monitor and document the QC of the analyses, and regular check sampling by a third-party analytical laboratory, including a description of the pass/fail criteria, and the actions taken to address results that are outside of the pass/fail limits (CIM 2018).

Securities regulators and financial institutions now demand that full QAQC procedures are used for all resource programs. There are various regulations and codes depending on where in the world the company has their primary stock exchange listing, such as SAMREC (South Africa), JORC (Australia) and NI 43-101 (Canada). These codes are all based on the standard definitions and globally consistent reporting requirements as determined by the Council of Mining and Metallurgical Institutions (CMMI) and the Committee for Mineral Reserves International Reporting Standards (CRIRSCO). These guidelines and standards are published and adopted by the relevant professional bodies around the world. They detail the mandatory requirements for disclosure of exploration results, reserves, resources, mineral properties, and require a summary of the nature and extent of all QC procedures employed, check assay, and other analytical and testing procedures utilized, including the results and corrective actions taken, in other words a Quality Assurance Program.

The purpose of these international reporting codes is to ensure that fraudulent information relating to mineral properties is not published and to reassure investors that projects have been assessed in a scientific manner. The impetus for developing these codes came from the Busang or Bre-X scandal (Indonesia) in 1997 (Wilton 2017).

Bre-X was a Canadian mining company based in Calgary, Alberta. In October 1995, they announced the discovery of one of the biggest gold deposits in the world. The estimates for this deposit climbed from 2 million ounces to a peak of 70 million ounces in 1997 with speculation of up to 200 million ounces, sending its stock price soaring from a penny share to a peak of CAD\$286.50 a share.

In March 1997 the project geologist, Michael de Guzman, fell to his death from a helicopter over the Indonesian jungle within days of Freeport-McMoran, a potential Busang project partner, announcing that its due diligence revealed only insignificant amounts of gold at the property. An independent third-party, Strathcona Minerals, was brought in to make its own analysis. On May 4th they published their results: the grade and tonnage of the deposit was

unsubstantiated and not based on scientific principles. The reporting was fraudulent, and the shares became worthless. It wiped out billions of dollars for many investors, which included major Canadian pension plans as well as individual investors who had committed their entire retirement funds, their children's college funds, and even mortgaged their homes. It turned out to be the biggest mining scandal of the century (Wilton 2017).

QA, Accuracy, Standards, and Control limits

Accuracy is a qualitative term referring to whether there is agreement between a measurement made and its accepted or reference value. Accuracy is determined using standards, also known as certified reference materials (CRMs) or standard reference materials (SRMs).

Within the geosciences CRMs and SRMs are manufactured materials, either from natural ores or blends of barren material and ore-concentrates, with a known concentration of the elements of interest. The “known” concentration is determined from a round robin involving replicate analyses of multiple aliquots from various labs. This consensus approach results in a recommended value determined from the means of accepted replicate values as well as confidence limits obtained by calculation of the variance of the recommended value (mean of means). These confidence limits are key in determining the upper control (UCL) and lower control limits (LCL) for the process control charts.

The selection of appropriate standards and blanks, and the accuracy and tolerance requirements that the analysis of those standards and blanks must fulfill as well as the precision of the replicate analyses is determined by the QA program.

A standard must be of a material as similar as possible to the samples being assayed to match the ore body mineralogy, ideally custom manufactured from in-house material, and

have a value that sits within the range used for classifying the material (i.e., typical waste values, ore-waste boundary, typical ore values). Given the deposit characteristics (i.e., oxide, sulfide, or various mineralization styles) and material processing requirements (i.e., leach, milling, etc.) several standards may be needed. A minimum of three is typically recommended.

Statistics and QA intersect around the description of pass/fail criteria of the quality controls that are put in place as part of the QA program to ensure accuracy and precision. Schewart Control Charts (Fig. 1.) are used to track the variation in repeated measurements of standard reference materials that is due to a defect or error in the process (i.e., contamination, equipment calibration, deviation from established operating procedures).

Definition of control limits or the natural boundaries of an analysis within specified confidence levels depends on the detection of outliers. When dealing with natural materials, which are expected to be inherently variable, the determination of control limits and detection of outliers in these materials can be a rather circular process. Additionally, identifying an observation as an outlier depends on the underlying distribution of the data, which is often assumed rather than known a priori.

An additional complication faced in the geosciences is that precision is a function of concentration and detection limit and, decreases as concentrations approach the detection limit of a given method. This will also impact what control limits can realistically be achieved for concentrations approaching the detection limits.

QA, Precision and Duplicates

Precision is defined as the amount of variation that exists in the values of multiple measurements of the same material/

Quality Assurance, Fig. 1 Example of a Schewart Control Chart for a standard reference material used to monitor variation in the analysis

parameter and is often expressed as the percent relative variation at the two-standard deviation (95%) confidence level. In this definition, the larger the precision number, the less precise the sampling and analysis. Precision is measured utilizing multiple analysis of standard reference material. Often precision is expressed as percent relative standard deviation (RSD) which is determined from the mean standard deviation of multiple analysis and the mean value of the analysis. Typically, a geological analysis requires $<10\%$ precision, that is that repeated measurements have no more than $\pm 10\%$ error.

In the context of QA precision is examined to assess measurement error and determine realistic control limits and provide a measure of analytical quality (Stanley and Lawie 2008). Statistical analysis of analytical duplicates, such as Thompson-Howarth plots (Fig. 2), are often used to help determine how the variation that is intrinsic to the process (i.e., normal lab variability, natural variability of the material) is a function of concentration and ensure the data is fit for purpose. The Thompson-Howarth method plots the mean of the duplicate pairs against an estimate of the standard deviation of the pair. Depending on the size of the datasets, there is a short method and a long method. From this a linear regression can be determined that expresses standard deviation as a

function of concentration, which can then be used to quantify precision at a given concentration (Thompson and Howarth 1978).

Challenges in QA Programs

One of the challenges that commonly arises during the establishment of any QAQC program involving geological systems is the inherent variability found in these systems, which is not known a priori, nor guaranteed to remain constant throughout the life of the project. With respect to this inherent variability outliers will often be encountered; these outliers are hard to recognize and avoid, particularly if the data is noisy or has poor precision to begin with.

Another challenge arises from the distribution of the data that is being examined. In fact, normally distributed errors are the exception rather than the rule in ore deposits and exploration datasets. Many of the common methods of error analysis assume these errors are normally distributed and can result in biased results and poor understanding of data quality when they are not (Stanley and Lawie 2008)

With the improvement of analytical methodology lower limits of detection are constantly being reached; however, in

Quality Assurance, Fig. 2 Example of a Thompson-Howarth long method plot describing error as a function of concentration

Quality Assurance,

Fig. 3 Example of a Thompson-Howarth long method concentration-precision plot that can be used to visualize the precision as a function of concentration. The LOD that is often quoted in analytical brochures reflects the $\pm 100\%$ precision, whereas the LOQ is what is important

geochemical exploration, geochemists are still pushing against these limits with both the materials we seek to characterize and the reference materials we choose to monitor QAQC with. Quite often geologists focus on the method detection limit (LOD), without understanding the limit of quantification (LOQ), that is the concentration above the background where a result is considered quantifiable and trusted (generally the 90th percentile for precision). Because precision is a function of concentration care must be taken to assure that the analytical method chosen results in data that is fit for purpose at the concentrations likely to be important for decision points, geological interpretations, and assumptions (Fig. 3). As a rule of thumb, this can be approximated as 10x the LOD quoted in the analytical brochures.

Summary

Quality assurance in geoscientific reporting centers around the selection of suitable labs and methods of analysis and the selection of appropriate standards and control limits for those standards. It defines the strategies in place for the management of quality as well as a description of the control limits, and the actions taken to address results that are outside of these limits.

QAQC; Quality control; Quality management; Quality systems

Definition

Quality control can be defined as “part of quality management focused on fulfilling quality requirements” (ASQ/ANSI 2008) by testing a sample of the output against the required tolerances or specifications as determined by the quality assurance requisites.

Often “quality assurance” (QA) and “quality control” (QC) are used interchangeably, referring to all the actions performed to ensure the quality of a product, service, or process. However, QA deals specifically with the setup of the systems and procedures that occur before a batch of samples is sent to the laboratory for analysis, and QC refers to the procedures and tools used to monitor these requirements for quality.

Why QAQC

Securities regulators and financial institutions now demand that full QAQC procedures are used for all resource programs. There are various regulations and codes depending on where in the world the company has their primary stock exchange listing, such as SAMREC (South Africa), JORC (Australia), and NI 43-101 (Canada). These codes are all based on the standard definitions and globally consistent reporting requirements as determined by the Council of Mining and Metallurgical Institutions (CMMI) and the Committee for Mineral Reserves International Reporting Standards (CRIRSCO). These guidelines and standards are published and adopted by the relevant professional bodies around the world. They detail the mandatory requirements for disclosure of exploration results, reserves, resources, and mineral properties and require a summary of the nature and extent of all QC procedures employed, including standards to monitor the quality of the analyses, and regular check sampling by a third-party analytical laboratory, including a description of the pass/fail criteria, and the actions taken to address results that are outside of the pass/fail limits in other words a Quality Assurance and Control Program (CIM 2018).

The purpose of these international reporting codes is to ensure that fraudulent information relating to mineral properties is not published and to reassure investors that projects have been assessed in a scientific manner. The impetus for developing these codes came from the Bre-X scandal in 1997 (Wilton 2017; see Quality Assurance). Bre-X, a Canadian company based in Calgary Alberta, announced the discovery of a large gold deposit in Busang Indonesia and triggering a rise in the stock price from pennies a share to CAD\$286.50 a share. The grade and tonnage of the deposit was discovered to be unsubstantiated and not based on data. It was the biggest mining scandal of the century (Wilton 2017) and wiped out billions of dollars for its shareholders, individuals, as well as Canadian pension plans.

QC Elements to Measure and Monitor Accuracy and Bias

In the geosciences, quality controls include replicate analyses of appropriate standards, blanks to measure accuracy and detect contamination, and regular monitoring of assays by an independent laboratory to identify bias.

Standards

Standards or standard reference materials (SRM) are certified materials inserted into the work order and used to assess the accuracy of the reported data. To be effective, these materials need to match the host rock and the mineralization style (matrix-matched), and efforts must be made to use various concentrations or grades (low, mid, and high) to provide relevant data over the range of reported assays.

Shewhart control charts (see Quality Assurance Fig. 1) are used to track the variation in repeated measurements of standard reference materials that is due to a defect or error in the process (i.e., contamination, equipment calibration, and deviation from established operating procedures). A control chart is plotted for each SRM in use, and assay data are plotted in time order along with the mean, an upper line for the upper control limit, and a lower line for the lower control limit. These lines are determined from a round robin involving replicate analyses of multiple aliquots from various labs. Typically, an SRM falling outside of 3 standard deviations from the mean signals a failure of control in the assay or measurement process. Two out of three successive measurements or assays of SRMs that are on the same side of the mean falling outside of 2 standard deviations will signal bias, another failure of control.

Blanks

Blanks are barren samples with an expected low concentrations or grade relative to the elements being evaluated and are used to check for contamination during sample preparation or

Quality Control, Fig. 1 XY-Scatter plot of primary assay data and umpire assay data showing RMA regression

assaying of elements. The ideal blank material is a hard, chunky barren material such as quartzite. Soft material is prepped more easily in the lab and will not thoroughly scour the equipment for smearing and residue of prior samples. If the material is too small (e.g., pea sized), it will not be crushed effectively and not be a thorough test for smearing of softer metals and residue left in the sample preparation equipment. Additionally, the sample size of blank material submitted must approximate the usual sample size because most laboratories will accept a >1% carryover of elements from one sample to the next, and this 1% carryover will be proportionally larger in a small blank – making the blank test ineffective.

SRM or Pulp Blanks are effectively another type of SRM with very low values of the element in question. These are inserted into the work order and used to assess contamination in the laboratory during sample analysis.

Blanks can be monitored on a chart like a Shewhart control chart, although there is no lower control limit and the upper control limit is defined as a multiple of the analytical detection limit, usually 5 times the analytical limit of detection for the method used.

Check or Umpire Assays

Check assays or umpire samples are pulverized samples (pulp) sent to a secondary lab and used to define inter-laboratory precision and bias. These should be selected to cover a range of concentrations representing the range of values encountered, with particular focus on values representing decision points (e.g., mining cut offs, ore routing, or dispatching triggers). It is expected that the primary lab and the secondary or umpire lab have less than 5% bias.

Inter-laboratory bias is identified by plotting the primary lab and secondary lab pairs on an XY-scatter plot. However, the data from the primary versus the secondary laboratory are independent of each other, and an ordinarily least squares (OLS) regression will correctly describe the relationship between the data because it assumes the X-measurement is without error.

The Reduced Major Axis regression line is the regression line that usually represents the most useful relationship between the X and Y axes. It assumes that both data sets are equally error prone and calculates the regression slope as the ratio of two standard deviations (Sokal and Rohlf 1995).

Quality Control, Fig. 2 A paired duplicate chart with control lines demonstrating the required precision ($\pm 10\%$) for the stage of duplicates

QC Elements to Measure and Monitor Precision

Sample duplicates are created at different stages of the workflow to monitor variability and detect errors related to geology, sampling, sample preparation and subsampling, and analysis. By inserting duplicates at these various points, it is possible to evaluate how much variability is contributed by these different processes.

Field Duplicates or Check Samples

Check samples or field duplicates are used to provide information on the reproducibility (or confidence) of the sampling, sample prep, and assaying program. They are another sample taken at the sampling site or in the case of diamond drill core a split (one half or one quarter) of the core. Field duplicate samples reflect the total variability or precision of the material being sampled, the sampling methodology, sample preparation, and analysis. The largest source of variability in field duplicates is related to geological heterogeneity and consistency in sampling and as such does not have pass/fail criteria,

rather they serve to monitor the adequacy of the sampling protocols.

Coarse Duplicates or Prep Duplicates

Coarse duplicates or prep duplicates reflect the variability introduced from the sample preparation procedures as well as the analytical precision. These duplicates are splits of a sample by the lab after the first comminution stage, typically the primary crushing. The largest source of error and variability in these duplicates is related to the subsampling process, that is, the crushing, the splitting of the crushed material, the pulverizing of that split, and the sampling of the resulting pulps. At each step, biases can be introduced by poor methodology, or the comminution and sampling stages may be insufficient to produce a representative subsample of the original sample, and as such they usually do not have pass/fail criteria, rather prep duplicates serve to monitor the adequacy of the sampling comminution and subsampling protocols.

Quality Control, Fig. 3 MPD plot with control lines demonstrating the required precision ($\pm 10\%$) for the stage of duplicates. The limit of detection is shown (LOD) as is the limit of quantification (LOQ). Any samples that are less than the LOQ are not reliable because the signal to

noise ratio of the analysis is too low. The samples greater than the LOQ suggest that the sample prep is not adequate (sample is not sufficiently homogenized) or there are problems with the analysis. In the case, the issue was determined to be the former

Analytical Duplicates or Pulp Duplicates

Pulp duplicates are used to provide information regarding analytical variation which exists in the analysis. These duplicates are splits or second aliquots of the final product of the sample preparation process, usually pulverization for rock and soil, that is analyzed side by side with the first. These duplicates will have pass/fail criteria, typically $\pm 10\%$, as they reflect the precision of the analysis and are used to monitor the quality of the analytical data and processes that are within the lab's control.

Analysis of QC Duplicates

Various graphical and statistical tools can be utilized to visualize and determine the quality of the data. A duplicate chart plots paired samples on an XY chart (Fig. 2). Control limits reflecting the required precision are also plotted. Typically,

the acceptable tolerance increases from $\pm 10\%$ for analytical duplicates, to $\pm 20\%$ for coarse duplicate, and $\pm 30\%$ for field duplicates, reflecting the increasing contribution of the sub-sampling (coarse duplicates) and geological variability (field duplicates) to the paired samples.

A mean percent difference (MPD) chart plots the mean concentration of the duplicate pair relative to the derived percent difference between the duplicate pair (Bland and Altman 1986). Control limits reflecting the required precision are also plotted (Fig. 3). These plots are used to provide a way of comparing the agreement between pairs and determine whether the degree of agreement is within required precision.

A relative difference plot or half absolute relative difference plot (HARD) ranks relative difference against percentile and is an effective tool only when there are a large number of pairs existing. Data will be deemed acceptable if a certain percentage of the data falls within specific tolerances; depending on the commodity or the mineralization system

Quality Control, Fig. 4 HARD plot for gold assay data from pulp duplicates. From this plot, it can be determined that 90% of the samples have greater than 20% variability, which suggests an unsatisfactory analysis or sample prep for this project

being investigated, this may be something like 90% of the data must have +10% precision (Fig. 4).

All the duplicate pairs can also be used in a Thompson-Howarth analysis (Thompson and Howarth 1973) to determine the effective precision as a function of concentration (see Quality Assurance Fig. 2). Separate curves expressing precision as a function of concentration can be constructed from each duplicate set to visualize precision at each stage from sampling (field duplicates) to sample prep (coarse or prep duplicates) to analysis (pulp duplicates). This will show where and at what concentration the largest variability in the sampling and analytical protocol is.

Challenges in QC Programs

Working with natural systems that have inherent variability always brings challenges. When dealing with trace element concentrations, the “nugget effect” or inability to start with a

representative sample can swamp out any variability in the analytical process making it difficult to monitor whether the analysis is in control or not.

To be effective, QC data must be reviewed on not only a “batch” basis, but also on longer timescales, such as monthly, quarterly, or at project milestones. Data trends such as drifts, shifts, bias, regular failures, and chronic sample prep issues (e.g., contamination) can only be fully realized when compiling data and reviewing longer time intervals.

Summary

Quality control refers to the procedures and tools used to monitor these requirements for quality by testing a sample of the output against the required tolerances or specifications as determined by the quality assurance requisites. Quality control can be viewed as the tools put in place for the measuring and detection of quality.

Quantitative Geomorphology

Vikrant Jain¹, Shantamoy Guha¹ and B. S. Daya Sagar²

¹Discipline of Earth Sciences, IIT Gandhinagar, Gandhinagar, India

²Systems Science and Informatics Unit, Indian Statistical Institute, Bangalore, Karnataka, India

Definition

Quantitative geomorphology is a part of geomorphology that explains landscape patterns, geomorphologic phenomena, processes, and cause–effect relationships for landforms on the Earth and Earth-like planetary surfaces in a firm quantitative manner. It demands frameworks to acquire spatiotemporal geomorphologic data, retrieve geomorphologic information, geomorphologic reasoning, and model simulation of geomorphologic phenomena and processes. Quantitative geomorphology is progressing in two dimensions. The structural dimension aims to characterize and explain landscape patterns, while the functional dimension focuses on processes, rates, and analyses of cause–effect relationships using fundamental concepts from physics. The approaches of

geometric, topological, and morphological relevance that show promise in the structural dimension of quantitative geomorphology include classical morphometry, hypsometry, and modern approaches such as fractal geometry, mathematical morphology, and geostatistics. Classical approaches employ source data such as river networks and elevation contours, especially digital elevation models (DEMs), to derive morphometric quantities. Development in the functional dimension of quantitative geomorphology helped to integrate (1) processes at different scales and (2) feedback mechanisms between different landforms (geomorphic systems). Further, the cause–effect relationship in a quantitative framework also leads to developing prediction capability, and hence, providing an important tool to discuss the future of geomorphic systems.

Scope of Quantitative Geomorphology

Geomorphologists have long ventured to identify landscape patterns and understand the events that cause changes in the landscape. The first set of queries related to landscape patterns started in 1950–1960, while the second dimension initiated in the late twentieth century was focused on process modeling and quantitative analysis of cause–effect relationship (Piégay 2019). Quantitative analysis of landscape patterns can be termed as the structural dimension of quantitative geomorphology that aims to quantitatively characterize landform or landscape features. However, current progress in quantitative geomorphology is in the area of process modeling and quantification of a cause–effect relationship, which defines the functional dimension of quantitative geomorphology. The growth in the functional dimension has seen the application of various mathematical tools to study various earth surface processes. Quantitative data on processes such as tectonics, climate, sea-level change, or human disturbances are essential to acquire an in-depth understanding of the cause–effect relationship and identify the causes. The geomorphic processes can be broadly classified into three main categories, e.g., erosion, transportation, and deposition. The primary agents that carry out these processes to modify the Earth’s surface are water, air, and ice. The prominent sources of energy to carry out the geomorphic processes are solar energy and gravitational forces. Solar energy drives other secondary forces like wind energy and generates water cycle. This wind drives the drag force to move sediments in the arid region and further generates waves that drive the geomorphic work in the coastal region. Gravitational force acts on the slope of the terrain in fluvial, glacial, and hillslope processes (Fig. 1).

The geomorphic systems are analyzed through a functional approach (through quantification of driving and resisting forces in a geomorphic system) or through an evolutionary approach to assess the landform or landscape trajectory with

Quantitative Geomorphology, Fig. 1 Generalized diagram of different forms of energy and resultant geomorphic processes

time. Functional approaches were built on the observation and measurement of landforms and fluxes, while evolutionary approaches were based on qualitative analysis or quantitative modeling approaches. Quantitative geomorphology has grown significantly in the last two decades with the advent of advanced techniques of remote sensing, especially digital elevation data, chronological methods (e.g., ^{14}C and OSL for the depositional environment; Cosmogenic nuclide e.g. ^3He , ^{10}Be , ^{26}Al for erosion rates and burial dating), and measurement of isotopes in water and sediments. Further, instrumentation procedures have led to in situ measurements of landform features and fluxes, while the experimental setup in the lab has generated huge quantitative datasets, which has led to several modeling approaches. Chronological tools provide a platform to analyze the process interaction, (dis)connectivity of different landscape drivers by various agents, integration of scales, and emergence of new geomorphic concepts like dis- or nonequilibrium landforms, nonlinearity, and complexity. Key aspects of quantitative geomorphology are discussed further.

Physical and Chemical Processes on the Earth's Surface

Rock Weathering

Weathering is an in situ process that mechanically fractures a rock body or chemically alters it with the help of water. A rock

mass undergoes weathering process and disintegrates into fractured, weathered, and subsequently mobilized by various geomorphic agents. The weathering processes can be divided into two main categories, i.e., physical weathering and chemical weathering.

Physical Weathering

Physical weathering is prominently a mechanical process where a whole rock body is extensively fractured and disseminate into smaller chunks of rocks. The fractured rock mass is further favorable for chemical disintegration and formation of saprolite. A rock body expands due to the heating process that inherently depends on the mineral content. If the stress due to expansion (or sometimes contraction) exceeds the strength of the rock, then it usually fractures and subsequently disintegrates. This expansion and contraction process due to temperature change is expressed by the volumetric thermal expansion coefficient, which is defined as $\alpha = 1/V(\frac{\partial V}{\partial T})_{CP}$, where V is the volume, T is temperature, and CP indicates constant pressure. The stress σ generated due to the strain is

$$\sigma = \frac{\alpha E \Delta T}{1 - \vartheta} \quad (1)$$

where E is the Young's modulus, ΔT is the temperature difference, and ϑ is the Poisson's ratio.

The rate of physical weathering is significantly important in arid or glacial regions due to the importance of expansion–

contraction of rock mass or frost cracking. The degree of weathering and generation of the loose sediment dictates the rate of sediment transport. Frost weathering is important as it enhances the efficiency of the rockfall in the alpine landscape (Draebing and Krautblatter 2019), whereas diurnal heating and salt weathering generate a significant amount of weathering material in the arid or semi-arid region (McFadden et al. 2005).

Chemical Weathering

The top surface of the Earth is constantly exposed to the atmosphere where it interacts primarily with air and water. This interaction leads to a change in the composition of the rock mass as chemicals present in the water interact with thermodynamically unstable minerals. This process is termed chemical weathering in which the minerals come to an equilibrium with the prevailing condition on the Earth's surface.

Apart from the alteration of the chemical composition of the rock, chemical weathering alters the physical property of the rock mass by lowering the strength of the material. The rate at which this alteration takes place is termed the chemical weathering rate. The most common process of chemical weathering is the conversion of the mineral state to form ion or dispersed colloidal molecular units. The simplest process of chemical alteration is the dissolution of the carbonate rock by water and atmospheric CO₂:

Equations 2 and 3 show the carbonate and silicate weathering reactions, respectively. Atmospheric CO₂ uptake during rock weathering is an important process that leads to global change in temperature. Previous research has shown a significant correlation between the silicate weathering rates and the CO₂ consumption rates (Gaillardet et al. 1999; Hartmann et al. 2009). Therefore, the quantification of silicate weathering rates is essential to understanding the carbon sequestration processes on a global scale. Carbon dioxide consumption rate corresponds to the flux of cations from the silicate weathering:

$$\text{CCR} = Q/A \cdot \sum (\text{Na}^+ + \text{K}^+ + \text{Mg}^{++} + \text{Ca}^{2+}) \quad (4)$$

where CCR is the carbon dioxide consumption rate, Q is the discharge in m^3s^{-1} , and A is the surface area of the same watershed in km^2 . The silicate weathering rate and CCR are

consistently higher in tropical watersheds (Gaillardet et al. 1999).

Chemical weathering index or indices of alteration are the quantitative representation of bulk major element oxide chemistry into a single value. Examples of common weathering indices are CIA (Nesbitt and Young 1982), R (Ruxton 1968), WIP (Parker 1970), PIA (Fedó et al. 1996), and CIW (Harnois 1988).

Hillslope Processes

Hillslopes constitute the basic element of any landscape where it generates and transport a huge portion of sediment to either fluvial or glacial system. Hillslopes are either bare bedrock or soil-mantled, and the form of the hillslope depends on the characteristics of the hillslope material. Most soil-mantled hillslopes are convex upward in nature, and diffusive hillslope processes are the most dominant mode of erosion. Erosion of a soil-mantled hillslope can be modeled with a simple two-dimensional diffusion equation (Fernandes and Dietrich 1997):

$$\frac{\partial z}{\partial t} = D \left(\frac{\partial^2 z}{\partial x^2} + \frac{\partial^2 z}{\partial y^2} \right) \quad (5)$$

where z is the elevation, D is the diffusion coefficient, x and y are the spatial coordinates, and t is the time. However, the soil-mantled hillslopes are mostly dominated by creep, which is a slow transport process. A generalized equation for creep is

$$\dot{\epsilon} = A\sigma^n \quad (6)$$

where $\dot{\epsilon}$ is the strain rate, and σ is the tensile stress. Further,

$$A = A' \frac{D_0 \mu b}{kT} \exp \left(-\frac{Q}{kT} \right) \quad (7)$$

where A' is a dimensionless, experimental constant, μ is the shear modulus, b is the Burgers' vector, k is the Boltzmann's constant, T is the absolute temperature, D_0 is the diffusion coefficient, and Q is the diffusion activation energy.

Apart from the slow diffusive hillslope processes, landslides are a very common case in the geomorphic system where the rapid downslope movement of materials takes place due to a sudden breach in the threshold condition. In the case of a planar segment of the hillslope, the weight of the overburdened material acts vertically and tries to shear the material away from the hillslope. The driving force on a section with width L and height h is

$$F_d = \rho(hdydx \cdot \cos \theta)g \sin \theta \quad (8)$$

where ρ is the bulk density of the material, g is the gravitational constant, and θ is the slope of the planar segment.

The resisting forces are essentially frictional forces due to contact with the overburdened material on the surface. The Frictional forces depends on the characteristics of grains of the material as well as of the surface. The resisting force is

$$F_r = [\rho(hdydx \cdot \cos \theta)g \cos \theta] \tan \phi \quad (9)$$

where $\tan \phi$ is the friction coefficient.

Therefore, the stress balance for a planar segment at the failure can be represented as a “factor of safety,” which is

$$F_s = \frac{[\rho_b g h \cos \theta \cos \theta - \rho_w g d] \tan \phi + C}{\rho_b g h \sin \theta \cos \theta} \quad (10)$$

where d is water table height above the failure plane, ρ_w is the density of water, and C is the cohesion of the material that restricts the failure. This simplistic equation of factor of safety provides quantitative information regarding the propensity of a hillslope for failure.

Geomorphic Agents and Their Actions

Fluvial Systems

Rivers are the most efficient conduit of water, sediment, and nutrients that shape the Earth's surface and sustain aquatic life (Fig. 2). A river generally occupies a valley, which may be a bedrock valley (bedrock rivers) with less amount of sediments on the channel or the river may flow over its alluvium (alluvial channels). A major shift in river science studies took place by

incorporating understanding from various disciplines, including hydrology, hydraulic engineering, physics, mathematics, water and sediment chemistry, ecology, sedimentary geology, and different approaches of numerical modeling. These have provided many datasets to further understand the driving mechanisms that cause changes in the processes and patterns. Water flows under the gravitational force and exerts driving forces for river processes. Furthermore, sediment supply in the channel and bedrock or alluvial characteristics (channel roughness) governs resisting forces for the erosion process.

Erosion in the fluvial system requires power exerted by the flowing water. This power is termed stream power, which is defined as the rate of energy conversion from potential to kinetic energy as water moves downstream (Bagnold 1966). It is expressed as

$$\Omega = \rho g Q s \quad (11)$$

where Ω is the stream power, ρ is the density of water (1000 kg/m^3), g is the acceleration due to gravity (9.8 m/s^2), Q is discharge (m^3/s), and s is the channel slope. However, the rate of energy expenditure on the river bed inherently depends on the channel width. Therefore, unit stream power is a more prominent measure of geomorphic work in a channel reach. Channel reach generally defines river characteristics for a length of around 8–10 times of channel width, which represents uniform characteristics of river channel. Unit stream power is expressed as

$$\omega = \Omega/w \quad (12)$$

Quantitative Geomorphology,

Fig. 2 Fluvial landscape and associated processes and landforms. The equation numbers correspond to the different processes. (Modified after Tucker and Slingerland 1994)

where w is the channel width. Empirical studies have shown that unit stream power is an effective metric to understand the sediment transport and erosion processes in a river channel. It also elucidates the significance of the channel width on channel processes (Yanites et al. 2010).

The water column exerts shear stress on the channel bed. Bed shear stress is calculated as

$$\tau = \rho g d s \quad (13)$$

where d is the average depth of the channel.

Furthermore, the shear stress and unit stream power are related as follows:

$$\omega = \tau V \quad (14)$$

where V is the average velocity of the water.

Hence, expressions of driving force vary with scale. Stream power, unit stream power, and shear stress represent the average value of driving force for a given channel length, cross section, or a given point in a cross section, respectively.

Water Flow and Sediment Scale Processes

Transportation of water is a classical fluid mechanics problem that is the basis of deriving the equations of vertical velocity profiles. These approaches can also be compared with traditional empirical equations (e.g., Manning's, Chezy, and Darcy–Weisbach equations). Navier–Stokes equation is used to solve the flow condition in open-channel flow. However, with a few assumptions (i.e., flow is steady, horizontally uniform, and flow is driven by gravity) the equation can be simplified as

$$g_x + \vartheta \frac{\partial^2 u}{\partial z^2} = 0 \quad (15)$$

where $g_x = g \sin \theta$, u is the horizontal velocity of water, z is the water depth, and ϑ is the viscosity of water (Anderson and Anderson 2010). Apart from this methodology, mean velocity is usually estimated with an empirical formula where Manning's equation is the most accepted.

$$v = \frac{k}{n} R_h^{2/3} S^{1/2} \quad (16)$$

where v is the mean cross-sectional velocity, R_h is the hydraulic radius, S is the channel slope, n is the Manning's roughness coefficient, and k is the unit factor (1 for SI units and 1.49 for English units).

Sediment is an important element in the fluvial system that shapes landforms, helps in enhancing nutrients, and sometimes causes havoc to human society. Sediment is usually transported either as bedload or suspended load. The most prominent method to empirically estimate bedload transport

rate is presented by Meyer-Peter and Müller (1948), which is as follows:

$$S_b \propto 8 \left(\left(\frac{k_r}{k'_r} \right)^{3/2} \tau^* - 0.047 \right)^{3/2} \quad (17)$$

where k_r is the roughness coefficient, k'_r is the roughness coefficient based on the grains, and τ^* is the dimensionless mobility parameter.

Suspended sediment load is primarily modeled by empirical power equations, e.g., sediment rating curves (Asselman 2000). However, the continuity equation is also utilized to estimate suspended sediment load and can be expressed as

$$\frac{\partial(AS)}{\partial t} + \frac{\partial(QS)}{\partial x} - \alpha w \omega (S - S_*) = 0 \quad (18)$$

where Q is the flow discharge, A is the flow area, S is the sediment concentration, S_* is the averaged sediment-carrying capacity, α is the adjustment coefficient for a cross section, and w is the water surface width (Zhang et al. 2014).

Reach Scale

River morphology is important to understand the connection between the channel and watershed. It also defines habitat for riverine ecology. Therefore, it is important to understand and quantify the causative factors of river morphology. Reach-scale studies of river morphology primarily focus on the effect of physical factors on the water and sediment transport in a river system. Unit stream power is the most effective measure of the driving force to understanding morphological processes (Eq. 12). A river reach can be represented in distinct categories. The most dominant patterns are braided, meandering, and anabranching. A braided river consists of a multiple channel network usually separated by a high amount of bedload deposited in a channel. A meandering channel on the contrary is a single-thread channel with multiple bends along its path. Anabranching channels are also multithread channels but fundamentally stable. Van den Berg (1995) suggested an empirical equation to separate single-thread and multithread channels based on a substantial dataset from natural channels:

$$\omega = 900 D_{50}^{0.42} \quad (19)$$

where ω is the unit's stream power at the transition between single-thread and multithread channels, and D_{50} is the median grain size. The sinuosity values also suggested that the higher gradient with higher unit stream power values results in a transition from single-thread to multithread channel (especially braided channels). Sediment characteristics govern resisting force. Chang (1985) expressed the grain size as

an important factor that leads to morphological changes in the natural river. The regression between $S/\sqrt{D}$ versus Q was used to understand the morphological characteristics of alluvial rivers.

The erosion process in an alluvial channel is usually modeled with Exner's equation:

$$\frac{\partial z}{\partial t} = \frac{1}{\rho_b} \frac{\partial Q}{\partial x} + \frac{\partial S}{\partial t} \quad (20)$$

where Q is the sediment transport rate as bedload, S is the suspended sediment, and ρ_b is the porosity factor (Anderson and Anderson 2010).

In the case of the bedrock rivers, the erosion processes at reach scale are modeling using an excess shear stress model:

$$E = K(\tau - \tau_c)^a \quad (21)$$

where τ is the bed shear stress, τ_c is the critical shear stress, and K and a are parameters. An implication of several studies has shown that Eq. 21 is a nonlinear equation that is dependent on the local slope and water discharge (Tucker and Hancock 2010).

Basin Scale

Apart from the reach-scale analysis, understanding of topographic and network characteristics at basin scale is important to quantify the topography. Morphometric analysis is perhaps the most established method to quantify, describe, and analyze landforms at different scales of studies. For the basin-scale studies, researchers have used morphometric analysis for several decades. These morphometric parameters are primarily linear or areal (Table 1).

Hypsometric curve and integral are also important to study drainage basin characteristics. Hypsometric analysis corresponds to the distribution of surface area to elevation. Hypsometric curves have been largely utilized to describe the flatness of a drainage basin surface. Hypsometric integral is the integration value of the hypsometric curve and estimated using the following expression:

$$\frac{V}{HA} = \int_0^1 x \, dy \quad (22)$$

where V is the total volume, HA is the entire volume of the reference area, $x = \frac{a}{A}$ (a is the area within a band of elevation; A is the total area of the basin), and $y = \frac{h}{H}$ (h is the relative elevation; H is the absolute elevation). This integral primarily describes the nature of the dissection of a landmass within a drainage basin (Strahler 1952).

River long profile is the fundamental feature to assess the spatial variability of fluvial processes. The shape of the long profile reflects the evolutionary trajectory of a fluvial system (Fryirs and Brierley 2012), and therefore, modeling the long profile has remained a fundamental question. Various functions like logarithmic, power, and exponential functions have been used to express the shape of long profiles. Jain et al. (2006) observed that natural river long profile shape could be better represented by the sum of two exponential functions:

$$Z = \alpha_1 e^{-\beta_f L} + \alpha_2 e^{-\beta_s L} \quad (23)$$

where Z is the elevation of the channel long profile at any point, L is the length from channel head up to any point along the river long profile, and α and β are constants and

Quantitative Geomorphology, Table 1 A list of morphometric parameters to assess the drainage basin characteristics

Category	Morphometric parameters	Definition/equation
Linear	Stream order	Method to assign a numeric order to links in a stream network
	Stream number (N_u)	Number of stream segments of order u
	Stream length (L_u) (km)	Length of stream of particular order
	Stream length ratio (L_{ur})	$\overline{L_u}/\overline{L_{u+1}}$
	Bifurcation ratio (R_b)	N_u/N_{u+1}
Areal	Basin length (km)	The linear distance between source to mouth of a river in a basin
	Basin perimeter (km)	Length of the basin boundary
	Form factor ratio (R_f)	A/L_b^2
	Elongation ratio (R_e)	$1.128\sqrt{A}/L_b$
	Circularity ration (R_c)	$4\pi A/P^2$
	Drainage density (D_d)	$\sum L_s/A$
	Drainage texture (T)	$\sum N_u/P$
	Stream frequency (F_s)	N_u/A
	Compactness coefficient (C_c)	$2(\sqrt{A/\pi})/L_b$

Total length of stream for (L_s), length of particular stream order (L_u), number of streams for particular stream order (N_u), drainage basin area (A), length of drainage basin (L_b), and drainage basin perimeter (P)

coefficients, respectively, of the exponential function (Sonam and Jain 2018).

The morphometric analysis has been effectively used to evaluate the geological or tectonic controls in a drainage basin (Różycka et al. 2021). The differential geometry has been effectively utilized to understand the tectonics and landslide processes (Jordan 2003). Recently, the application of fractals on morphometric data also highlighted the role of lithology on landscape characteristics (Sahoo et al. 2020).

Morphometric characteristics define the physical characteristics of a river basin and can also be utilized to understand the hydrologic response utilizing geomorphologic instantaneous unit hydrograph (GIUH). GIUH is the probability density function for the time of arrival of a raindrop, randomly placed at any point in the watershed (Rodríguez-Iturbe and Valdés 1979; Jain and Sinha 2003). The general equation of GIUH for an N th-order stream can be derived by application of semi-Markov process on the drainage network and is written as

$$\frac{d\theta_{N+2}(t)}{dt} = \sum_{i=1}^N \theta_i(0) \frac{d\varphi_{i(N+2)}(t)}{dt} \quad (24)$$

where $\theta_{N+2}(t)$ is defined as the probability that the drop is found in the state $(N+2)$ at the interval “ t ,” and “ $N+2$ ” represents the final state at the basin outlet; $\theta_i(0)$ is the probability that the transport of the drop starts at state “ i ”; and $\varphi_{i(N+2)}(t)$ is the interval transition probability from state “ i ” to state $N+2$.

GIUH is efficient model for predicting direct runoff based on Horton’s stream-order ratio and kinematic wave theory. Additionally, the model can also depict the role of geomorphic characteristics in the flood hazard. Length ratio and length of the channel of maximum orders are proved to be the most effective control on the hydrologic response of a drainage basin in the Himalayan setting (Jain and Sinha 2006). The knowledge of the hydrologic response of a drainage basin subsequently helps to better model the response of an ungauged drainage basin.

Aeolian Systems

Aeolian processes in the arid region are primarily controlled by the action of wind, which is essentially a form of incoming solar energy in terms of a pressure gradient (Fig. 3). Apart from solar energy, the wind is also generated due to the Earth’s rotation and surface irregularities. Erosion and sediment transport processes in the arid region are primarily quantified by wind velocity and shear stress. Sediment is first entrained by the shear stress of the wind by overcoming the particle weight and cohesion. Bagnold (1941) first presented the simplified model representing a critical wind shear for a particular grain size:

$$u_{*ct} = A \sqrt{\frac{(\sigma - \rho)}{\rho}} g.d \quad (25)$$

where u_{*ct} is the critical shear stress, A the constant dependent upon the grain Reynolds number, σ is the particle density, ρ is

Quantitative Geomorphology, Fig. 3 Aeolian landscape consisting of major landforms associated with processes. The equation numbers correspond to the different processes

the wind density, g is the acceleration due to gravity, and d is the grain diameter.

After the selective entrainment, the sand grains are transported either via saltation or suspension. A general model for the transportation of sediment is therefore the function of the grain size, though a general model of sediment transport should incorporate a range of grain sizes and variable wind speed. Therefore, in a given shear velocity of the wind, larger grains are transported via saltating trajectories and finer grains follow suspension trajectories. Four main forces act on the sand particle: (1) body force due to gravity, (2) aerodynamic drag force, (3) aerodynamic lift force, and (4) Magnus lift due to the spin of the particle (Anderson and Hallet 1986).

Empirical models are also used to predict wind-driven transportation processes. One such model is the Rodok model, which is a fully empirical model that is particularly used to model the movement of fine particles. Whenever the wind velocity exceeds the threshold of sediment entrainment, this model is applicable (Leenders et al. 2011). The model is given as

$$F_e = a_1 e^{b_1 u_*} \quad (26)$$

where F_e is the flux of sediment, u_* is the shear velocity of wind, and a_1 and b_1 are the empirical constants. Further, physics-based equations have also been used to understand the sediment flux in the arid and semi-arid regions. A dynamic mass balance approach is applied to the sediment transport problem. The model suggests an increase in the flux when the horizontal wind velocity exceeds the threshold of the entrainment of the sand grain. Experimental studies have shown that the dynamic mass balance approach provides a better means to quantify the sediment flux (Mayaud et al. 2017). Furthermore, this model provides temporal-scale variation of sediment transport mechanisms. Dynamic mass balance model is given as

$$\frac{dQ_{ip}}{dt} = H \left[a_1 (u - u_t)^2 \right] - \left(\frac{Q_{ip}}{\left(\frac{b_1 d}{D} + \frac{c_1 u}{u_t} \right)} \right) \quad (27)$$

where Q_{ip} is the predicted mass flux for the given time interval, u is the mean horizontal wind velocity over the given time interval, u_t is the horizontal wind velocity threshold, d is the grain diameter (mm), D is a reference grain diameter, a_1 is the constant with dimension, b_1 and c_1 are dimensionless constants. Integrated wind erosion modeling system (IWEMS), on the other hand, provides a quantitative prediction of wind erosion from local to global scale (Lu and Shao 2001). This model incorporates physics-based as well as empirical equations that takes care of starting from particle entrainment to deposition. Researchers have observed that

these integrated models provide a better means to simulate the effect of dust storms over a large area (Lu and Shao 2001).

The grains that are entrained and transported eventually get deposited when the gravitational force acting on the grains overcomes the shear stress force. However, the rate of settling of particles in fluid flow (water and air) also depends on the density and viscosity of the transportation agents following Stoke's law. Furthermore, vegetation also plays a major role in the sediment deposition processes by disturbing the wind velocity profiles by acting as a roughness on the surface.

Glacial Systems

Glaciers are the accumulated body of ice that moves downstream due to the weight of the ice and the slope of the surface under the gravitational forces (Fig. 4). Glacial systems have been used as markers of climate change because the change in the mass of ice in the glacier dictates temperature change (Vuille et al. 2008). Depending on the thermal regime, glaciers can be categorized into two types: (1) cold-based glaciers and (2) warm-based glaciers. Cold-based glaciers have the basal part entirely below the pressure melting point and are therefore also termed "dry-based glaciers." The temperature at the base is characterized by subzero temperature. Warm-based glaciers or temperate glaciers are characterized by the temperature at 0° or above the melting point. Warm-based glaciers slide over a thin sheet of water and under the gravitational force through internal deformation. Whereas the cold-based glaciers move through internal deformation only. Basal sliding velocity is modeled as a function of basal shear stress (τ_b) (driving force) and effective normal stress (N) (resisting force):

$$U_b = k \tau_b^m N^{-p} \quad (28)$$

where m and p are positive constants, k is a sliding parameter, and N is the effective normal stress that is the difference between ice overburden and the basal water pressure (Raymond and Harrison 1987). Empirical data also support that the erosion rates are positively correlated to the basal sliding velocity across the globe (Cook et al. 2020).

The glacial erosion rate is generally assumed to be proportional to the sliding velocity of the ice in the glacial valley. Bedrock surface erosion rate (E) is estimated as

$$E = e_c T U_b^{e_v} \quad (29)$$

where e_c is erosion rate constant, T is the time-step size, U_b is the sliding velocity, and e_v is an erosion exponent (Harbor 1992).

The flow of ice behaves as non-Newtonian fluid where strain rate and shear stress are nonlinearly related:

Quantitative Geomorphology, Fig. 4 Glacial landscape and processes. The equation numbers correspond to the different processes

$$\frac{du}{dz} = a \left(\frac{\tau}{\tau_0} \right)^n \quad (30)$$

where u is the fluid velocity, z is the distance along the profile, τ is the shear stress, τ_0 is a reference or yield stress, and a and n are rheological parameters. The values of a and n may be constant in some cases but practically depend on the temperature or density of the flow (Pelletier 2008).

Sediment transport in the glacial system happens via (1) debris-rich ice transport or (2) transport by meltwater. However, most sediment transport occurs by meltwater, which is characterized as glacio-fluvial sediment transportation (Delaney et al. 2018). The study utilized an empirical power-law function between the bedload and discharge from the melt. Additionally, a substantial mass of the sediment is also transported supraglacially or within the ice mass. These piles of sediment are only visible below the equilibrium line. One of the primary sources of sediment in glacial streams is the debris transported by the ice and subglacial rivers.

Depositions in the glaciated region consist of poorly sorted grains, primarily called “tills.” A distinctive depositional feature in the glacial valley is eskers. Eskers represents the landform where subglacial tunnels swiftly transport water and coarse sediments. The equation for the potential field that is the total head is described as follows (Anderson and Anderson 2010):

$$\Phi = \rho_w g z + \rho_i g (H - (z - z_b)) \quad (31)$$

where z is elevation, z_b is the elevation of the bed, and H is the thickness of the ice. Water is transported along a line perpendicular to the line of equipotential:

$$\frac{d\Phi}{dx} = \rho_w g \frac{dz}{dx} + \rho_i g \frac{d(H - (z - z_b))}{dx} = 0 \quad (32)$$

The expression for the potential gradient along the interface of ice and rock is

$$\left. \frac{d\Phi}{dx} \right|_{bed} = (\rho_w - \rho_i) \frac{dz_b}{dx} + \rho_i g \frac{dz_s}{dx} \quad (33)$$

where z_s is the elevation of ice surface. The term bed slope can be written as a function of the slope of the ice surface as

$$\frac{dz_b}{dx} < -11 \frac{dz_s}{dx} \quad (34)$$

Overall, the slope of the glacier, temperature dynamics, and glacio-fluvial interaction governs the depositional characteristics.

Coastal Processes

Coastal regions are one of the most dynamic landscapes. The coastal landscapes are prominently shaped by the oceanic surface waves (driven by wind energy) and the tides (driven by the gravitational attraction of the Moon and the Sun). The change in climatic conditions marks the imprint on the coastal geomorphology through the change in the geomorphic processes driven by the aforementioned agents. Contemporary as well as ancient depositional features record the period of sea-level changes, which is a marker of climate change. Wave energy is the most important geomorphic agent in the coastal system. The surface waves originate when the wind energy is transferred to the ocean surface. Therefore, strong wind-storms are a causative factor of higher-amplitude waves.

The wave energy transported toward the coastal region in the form of oscillatory waves on the beach area leads to substantial modification of the physical features. The energy per unit length of wave or the energy density may be written as

$$E = \frac{\rho g H^2}{8} \quad (35)$$

where H is the wave height, ρ is the density of ocean water, and g is the gravitational constant.

The mean potential energy is

$$\overline{PE} = \frac{\rho g h^2}{2} + \frac{\rho g H^2}{16} \quad (36)$$

Here, the first term is the mean potential energy associated with the water column height above the ocean surface and the second term represents potential energy associated with the wave (Holthuijsen 2010).

The flux of energy or the power of the wave is the product of the energy density with the group wave speed:

$$\omega = \frac{\rho g^{3/2}}{8} H^2 h^{1/2} \quad (37)$$

Wave energy is further transformed into currents, which aid in transporting and depositing sediments in the beach area. Coastal barriers are generally formed by shore-parallel transportation of sand and gravels. The most used empirical equation for the longshore drift is (Komar 1998)

$$Q_{\text{long}} = 1.1 \rho g^{3/2} H_{\text{br}}^{5/2} \sin \alpha_{\text{br}} \cos \alpha_{\text{br}} \quad (38)$$

where H_{br} is the height of the breaker, g is the acceleration due to gravity, ρ is the density of water and the sediment transport rate Q_{long} , and α_{br} is the angle between the breaker line and local shoreline. Although this mathematical model proved to be the proper justification of the physics of the movement of grains, real-time estimation of sediment transport is extremely difficult to comprehend. Therefore, these are usually achieved by measuring the actual amount of loose sediments trapped behind man-made structures.

Deltas are the other important landform that forms when the river enters the sea. Deltas are primarily important because of the diverse flora and fauna. The formation of the delta can be examined by using the continuity equation of sediment (Eq. 20).

Although this simplified formulation provides meaningful results, the shape and sedimentology largely depend on the water density difference, shape of the continental shelf, and amount of sediment in the channel. Therefore, modeling of deltas remains an important problem to date (Takagi et al. 2019).

Landscape Patterns and Process Interactions

Mathematical Morphology in Quantitative Geomorphology

Terrestrial surfaces of Earth and Earth-like planets exhibit variations across spatiotemporal scales. Understanding the organizational complexity of such terrestrial surfaces and associated features both across spatial and temporal scales leads to a study of interest to quantitative geomorphologists. Quantitative geomorphology, which gained wide attention from the classical geomorphologists, was popularized through Horton–Strahler’s contributions to morphometric and hypsometric analyses, respectively, carried out on two fundamental topological quantities, namely, river networks and elevation contours. The main source of these two quantities was topographic maps. However, the data, in particular, DEMs, available at multiple spatial scales, offer numerous advantages over the topographic maps but also pose challenges to the quantitative geomorphologists. The DEM data have rich geometric, morphological, and topological (GMT) relevance immensely useful in quantitative geomorphology. To develop a cogent spatiotemporal model, well-analyzed and well-reasoned information retrieved from spatiotemporal data are important ingredients (Sagar and Serra 2010). Such models are essential to understanding the dynamical behavior of terrestrial surficial processes in a firm quantitative manner. Three ways of understanding complexity involved in spatiotemporal behavior of terrestrial surfaces and associated phenomena include considering (1) topographic depressions and their relationships with the rest of the surface, (2) unique topological networks, and (3) terrestrial surfaces. The three features of geomorphologic relevance represented in mathematical terms as functions, sets, and skeletons are respectively surfaces, planes, and networks. From the context of geomorphology, some examples of such functions, sets, and networks include DEMs, water bodies, and river networks (Sagar 2020). Mathematical morphology (Serra 1982; Matheron 1975) offers an approach to deal with all the intertwined topics.

With the advent of powerful computers with high-resolution graphics facilities and the availability of DEMs, a new set of mathematical approaches offered quantitative geomorphologists insights. One of such mathematical approaches is mathematical morphology (Serra 1982) originally popular in shape and image analysis studies. Mathematical morphology offers numerous operators and transformations – named after terms stemming from the literature of the Earth Sciences (Beucher 1999) – to deal with retrieval of information from DEMs, quantitative characterization of DEMs, quantitative reasoning of the information retrieved from DEMs, modeling, and simulation of various surficial processes that involve DEMs, and spatiotemporal visualization of various surficial phenomena and processes.

Initial impetus for quantitative geomorphology through the applications of mathematical morphology was given by Sagar (1996, 2013). For the retrieval of GMT quantities from the DEMs, quantitative analysis of DEMs and GMT quantities thus retrieved from the DEMs, quantitative spatiotemporal reasoning of those retrieved quantities, modeling and simulation, as well as visualization of spatiotemporal behavior of geomorphologically relevant phenomena and processes, mathematical morphology offers numerous operators, transformations, algorithms, and frameworks. Some of the transformations, to name a few, include

- Skeletonization to extract topological quantities such as the ridge, the valley connectivity networks (Sagar et al. 2000, 2003), mountain objects (Dinesh et al. 2007), and the hierarchical watersheds (Chockalingam and Sagar 2003) from the DEMs that would be eventually used in the terrestrial surface characterization.
- Morphological distances in classification and clustering of geomorphologic units such as basins, sub-basins, and watersheds represented in planar form (Vardhan et al. 2013) and terrestrial surficial data represented in DEM form (Sagar and Lim 2015).
- Multiscale morphological operations, skeletonization by zones of influence (SKIZ), morphological pruning, thinning, thickening, and Hit-Or-Miss Transformation were employed in deriving a host of allometric power-law relationships in channel networks, water bodies, watersheds, and several other geomorphologic phenomena (Tay et al. 2005a, b, c; Sagar and Tien 2004; Sagar and Chockalingam 2004; Nagajothi et al. 2021). The characterization via a set of derived power-law relationships highlighted the evidence of self-organization via scaling laws – in networks, hierarchically decomposed sub-watersheds, and water bodies and their zones of influence, which evidently belong to different universality classes – which possess excellent agreement with geomorphologic laws such as Horton's laws, Hurst exponents, Hack's exponent, and other power-laws given in non-geoscientific context (Sagar 1996, 1999, 2000a; Sagar et al. 1998a, b, 1999). This aspect is further extended based on intuitive arguments that these universal scaling laws possess limited utility in exploring possibilities to relate them with geomorphologic processes. These arguments formed the basis to provide alternative methods that yield scale-invariant but shape-dependent power laws.
- Morphological shape decompositions in the characterization of hillslope region by deriving scale-invariant but shape-dependent measures (Sagar and Chockalingam 2004; Chockalingam and Sagar 2005) to quantitatively characterize the spatiotemporal terrestrial complexity that explains the commonly sharing physical mechanisms involved in terrestrial phenomena and processes.
- Granulometries in surficial roughness characterization of the basins and watersheds partitioned from the DEMs (Tay et al. 2005c, 2007; Nagajothi and Sagar 2019).
- Multiscale openings and closings in the modeling of the geomorphologic processes, in discrete space, under the perturbations caused due to cascade forces (flood–drought, expansion–contraction, uplift–erosion, protruding–flattening, and shortening–amplification) in a nonlinear fashion mimicking the realistic situations (Sagar et al. 1998b). Morphological modeling of the geomorphologic phenomena and processes provides unique contributions to simulations of geomorphologic networks (Sagar et al. 1998a, 2001), terrestrial surfaces (Sagar and Murthy 2000), water bodies and sand dunes (Sagar 2000b, 2001) laws of geomorphic structures under the perturbations created through an interplay between numerical simulations and graphic analysis (Sagar et al. 1998b), and understanding spatial and/or temporal behaviors of certain evolving and dynamic geomorphic phenomena (Sagar 2005).
- Morphological interpolations, which provide an effective way to transform sparse data and/or information into dense data and/or information (Sagar 2010; Sagar and Lim 2015; Challa et al. 2018), in spatiotemporal visualizations of (geomorphologic) phenomena. While developing spatiotemporal geomorphologic models that provide a better understanding of the behavioral patterns of the geo(morpho)logic phenomena and processes, the availability of the relevant data at the time intervals as close as possible is important.

Mathematical morphology – A robust mathematical theory offers a plethora of operations and transformations that provide the opportunity to transform the way quantitative geomorphologists examine terrestrial surfaces. Applications of numerous mathematical morphological transformations, which are new to the geomorphologic community, provide insights for quantitative geomorphologists. For the illustrations appropriate for section “[Mathematical Morphology in Quantitative Geomorphology](#)”, the reader may refer to the relevant cross-referenced chapters.

Landscape Evolution Models (LEMs)

The geomorphic studies explain the origin and dynamics of the topography over the Earth's surface. Various physical and chemical processes, along with actions of different geomorphic agents at long time scales, lead to variability across the landscape. Tools in mathematical morphology are usually utilized to quantitatively characterize a landscape and its trajectory with time (Fig. 2). Further, to explain the time-dependent evolution of the topography, there is a need to model the evolution processes mathematically. LEMs integrate the dynamics of the different landforms to develop the evolutionary trajectory of landscape with the help of various

equations corresponding to different processes at the landform scale. LEMs consider spatial locations as grids or TINs, and output from the equations flows across the grid to develop a feedback mechanism in a landscape. LEM not only explains the temporal variation of a landscape but more generally indicates a process–response system due to the interaction of landform and formative processes. LEM aims to describe the changes in the aggregate of landform shape, size, and relief over the smallest to the largest spatial scale. Integration of scales is a major challenge in the geomorphic system. The mathematical expressions of landscape and its constituent landforms help to integrate the processes at different scales in a given landscape and provide an evolutionary trajectory of landscape or explain major landscape pattern. The landform-scale equations are mostly derived from the functional approach, while its integration leads to the evolutionary trajectory of the landscape. Hence, LEMs not only integrate processes at different scales, but also help to integrate two approaches of geomorphic studies, i.e., functional and evolutionary approaches.

Various governing equations for landscape evolution are too complex to obtain coupled closed-form solutions, and therefore, numerical solutions methods are necessary to obtain the solutions. LEMs generally require the following steps: (1) continuity of mass, (2) geomorphic transport equations for movement of water and sediment, and (3) equations for erosion, transport, and deposition by geomorphic agents (Tucker and Hancock 2010). Continuity of mass is expressed as

$$\frac{\partial \bar{\rho} \eta}{\partial t} = \rho_{sc} B - \nabla \cdot (\rho_s \mathbf{q}_s) \quad (39)$$

where η is the height of land surface relative to a datum, t is time, $\mathbf{q}_s$ is a vector depicting transport rate, B is a source term (maybe uplift or subsidence), ∇ is the divergence operator, $\bar{\rho}$ is the average density of rock/sediment, and ρ_{sc} is the density of source materials.

Geomorphic transport functions are the main component of any numerical LEM. The theory of landscape evolution, therefore, requires complete knowledge of weathering, biological activities, and action of other geomorphic agents. Anderson (2002) presented a simple approach:

$$\frac{dz_b}{dt} = \min[P_{s0} + bH, P_{s1} \exp(H/H^*)] \quad (40)$$

where $\frac{dz_b}{dt}$ is the rate of weathering, “min” is “take the minimum of,” P_{s0} is the production of bare bedrock, b scales the production rate increase due to increase in thickness of regolith, P_{s1} defines the intercept of the exponential decay, and H^* scales the exponential decline of weathering rate for large

regolith thicknesses. This equation shows that if the thickness of regolith decreases below a critical thickness, the rate of production also decreases. Although this exponential decay rule successfully predicts the weathering processes, there is a further need to include the physiochemical processes of weathering to establish mathematical models in landscape evolution.

The movement of water and sediment is another problem in landscape evolution modeling. In the low-slope region, soil creep is a primary factor that transports the sediment down the slope. A simple linear or nonlinear equation (Eq. 6) for creep is utilized to model the creep. Although this equation can explain the transport of materials, this does not explain the fast transport on the higher slope. This further needs a nonlinear transport function as follows:

$$\mathbf{q}_s = \frac{K_D \eta}{1 - (|\nabla \eta| S_c)^a} \quad (41)$$

where S_c is the threshold gradient that represents the point of failure (Howard 1994; Roering et al. 1999).

Rivers are another important feature of a landscape at a larger spatial scale. The erosion driven by the water in a river depends on the ability to transport large materials and erode its bed. The detachment limited model offers to model the river processes where the sediment is efficiently transported downstream. Expression of the 1D detachment limited erosion model is

$$\frac{\partial h}{\partial t} = U - K A^m \frac{\partial h^n}{\partial x} \quad (42)$$

where h is elevation, and U is the uplift rate. The term $K A^m \frac{\partial h^n}{\partial x}$ represents channel incision as a function of driving force (Eqs. 11–13), where basin area is used as a proxy for discharge, and K is the erodibility parameter. The rate of erosion per unit time E depends on the excess bed shear stress (Eq. 21).

Bed shear stress is also responsible for sediment transport processes (Eq. 17). The overall 1D model for landscape evolution with detachment limited stream power model and linear hillslope diffusion model can be expressed as

$$\frac{\partial h}{\partial t} = U - K A^m \left| \frac{\partial h}{\partial x} \right|^n + D \frac{\partial^2 h}{\partial x^2} \quad (43)$$

where D is the diffusion coefficient.

Isostatic rebound is another important component in the LEM. Isostatic rebound can be associated with surface erosion where the topography is relaxed due to the removal of surface load:

$$D \left(\frac{\partial^4 w}{\partial x^2} + 2 \frac{\partial^4 w}{\partial x^2 \partial y^2} + \frac{\partial^4 w}{\partial y^4} \right) = \Delta \rho g w + \rho_s g \Delta h \quad (44)$$

where w is the surface displacement due to isostatic adjustment owing to increment of erosion Δh , ρ_s is the density of rocks at the surface, $\Delta \rho$ is the density contrast between the surface and asthenosphere, and D is the flexural rigidity. Studies have shown that without tectonic components the landscape can be elevated by several hundreds of meters with isostatic adjustment due to denudational unloading (Gilchrist and Summerfield 1990).

These equations are usually solved with the help of different numerical methods. These equations are always coupled equations, and therefore, they can be simply solved by an explicit finite difference scheme. However, research has shown that implicit methods are also very efficient and do not require several checks for the stability of the solution (Braun and Willett 2013; Fagherazzi et al. 2002). Currently, Landlab is one of the most widely used Python-based numerical LEMs that solves various problems of surface, subsurface, and biological processes (Barnhart et al. 2020). Landlab numerical model contains different separate process components that can be integrated for high spatial and temporal resolution problems. Large spatiotemporal-scale models aided by the availability of big data are the current trend in this field of research. Although highly complex models are necessary for obtaining significant results, they are not sufficient to model highly complex natural processes. Therefore, all models have uncertainty. The important step to overcome the issue of uncertainty is to focus on the correctness of building a model as close as possible to reality. However, an increase in the complexity does not necessarily provide better or desired results; rather, this can attenuate important model outcomes.

Geomorphic Connectivity

In recent times, the concept of connectivity is an emergent property of geomorphic systems (Wohl 2017). Any geomorphic system is composed of different landforms, and there exists a hierarchical link between the operative geomorphic processes (Brierley et al. 2006). The term connectivity can be defined as the efficiency of the water, sediment, and nutrient transport from one component to another. Therefore, the study of geomorphic connectivity provides an opportunity to understand the interrelationship and interdependencies of the components (landforms) of a geomorphic system (landscape). Wohl et al. (2019) have explained three types of geomorphic connectivity: (1) sediment connectivity, (2) landscape connectivity, and (3) hydrologic connectivity. The nature of connectivity could be structure-based (structural connectivity) or process-based (functional connectivity) (Jain and Tandon 2010; Wainwright et al. 2011).

Quantification of connectivity and prediction remains a major research question for the last couple of decades. A major focus has been given to quantifying the functional connectivity of sediment through a different element of a landscape (e.g., hillslope to rivers). Connectivity index (IC) based on an empirical approach is a common tool to quantitatively express the nature of connectivity in a landscape. A commonly used IC for a river basin is expressed as (after Borselli et al. (2008))

$$IC = \log_{10} \left(\frac{D_{up}}{D_{dn}} \right) \quad (45)$$

where D_{up} and D_{dn} are upslope and downslope components of connectivity, respectively. The upslope component of sediment connectivity is the potential for the downslope movement of the available sediment and is estimated as

$$D_{up} = \overline{W} \overline{S} \sqrt{A} \quad (46)$$

where $\overline{W}$ is the average weighting factor of the contributing area in the upslope, $\overline{S}$ is the average slope of the upslope area, and A is the contributing area.

D_{dn} is the component that considers the flow path length for a particle to reach the immediate sink and is estimated as

$$D_{dn} = \sum_i \frac{d_i}{W_i S_i} \quad (47)$$

where d_i is the length of the flow path along the i th cell following the steepest downslope direction, and W_i and S_i are the weighting factor and gradient of the i -th cell, respectively. Cavalli et al. (2013) suggested further modification to the slope factor, upstream contributing area, and weighting factors and suggested that these simple methods can help to understand the sediment dynamics in a very complex morphodynamic system. They also suggested that the sediment delivery pathways, amount of vegetation, and channel bed morphology are other important factors for understanding the connectivity.

Recently, the application of graph theory to quantify connectivity resulted in new insights into the sediment mobilization process. Heckmann and Schwanghart (2013) pioneered an approach to describe the geomorphic system as a network consisting of nodes (sediment sources) and edges (links between geomorphic processes). A graph with n nodes can be represented as $n \times n$ adjacency matrix A . Depending on the topological and spatial characteristics, the fluxes are associated with the edges that transport the sediment from upstream to downstream. The betweenness centrality index (B) is the measure of the extent to the presence of a node (i) between other nodes:

$$B_i = \frac{\sum n_{ijk}}{n_{jk}} \quad (48)$$

where n_{ijk} is the number of edges or path that is present between node j and node k and that pass through i , and n_{jk} is the total number of edges or paths between node j and node k .

The Shimbel index (Shi) is the factor that considers the distance between nodes and checks if the location of the nodes changes the total possible paths within the network:

$$Shi_i = \frac{\sum d_{ij}}{\sum d_{jk}} \quad (49)$$

If the Shimbel index is high, then the node contributes to creating long paths within the network; if the Shimbel index is low, then the compactness of the network is maximized by the nodes (Cossart and Fressard 2017). For the local scale, the network structural connectivity index is developed based on the potential fluxes and the accessibility of the transportation of flux (Cossart and Fressard 2017).

$$NSC_i = \frac{F_i}{Shi_i} \quad \text{and} \quad F_i = \frac{\sum F_{ijo}}{\sum F_{jo}} \quad (50)$$

F_{ijo} and F_{jo} are calculated from the reconstruction of sediment pathways throughout the cascade. These methodologies have successfully described the scale-dependent sediment mobilization and delivery behavior in a catchment. Additionally, as the graph theory also considers the structural connectivity between the nodes (or sediment sources), hotspots of geomorphic works can be identified.

Critical Zones

The topmost layer of the Earth's surface, i.e., from the bedrock to the lower atmosphere, is termed "critical zone" (Fig. 5). This term was introduced by the National Science Foundation (NRC 2001), defined as "... the heterogeneous, near-surface environment in which complex interactions involving rock, soil, water, air and living organisms regulate the natural habitat and determine availability of life-sustaining resources" (NRC 2001). Therefore, this zone connects the atmosphere, lithosphere, hydrosphere, and biosphere for various physiochemical processes. The experimental setup to study this thin layer is known worldwide as critical zone observatories (CZO). Recently, several CZOs were set up around the world to understand the

Quantitative Geomorphology,

Fig. 5 Schematic diagram showing major components of critical zone observatory. (Modified after Riebe et al. 2017)

coupled processes and their outcome on the natural world (Godd  ris and Brantley 2013).

Mathematical models for the critical zone are essentially needed to quantify the rate of weathering and soil production in order to address soil sustainability. Therefore, an integrated model has been established to link the soil formation, nutrients' transport, and transport of water (Giannakis et al. 2017). The water flow is expressed by Richard's equation:

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z} \left(k \frac{\partial h}{\partial z} \right) + S \quad (51)$$

where θ is the volumetric water content, t is time, z is the vertical coordinate, k is the unsaturated hydraulic conductivity, h is the pressure head, and S is the source of water. A knowledge-based reactive transport model is generally used to understand the time-varying water saturation (Aguilera et al. 2005). Representation of 1D continuum coupled mass transport and chemical reactions can be expressed mathematically as

$$\xi \frac{\partial C_j}{\partial t} = \left[\frac{\partial}{\partial x} \left(D \cdot \xi \cdot \frac{\partial C_j}{\partial x} \right) - \frac{\partial}{\partial x} (v \cdot \xi \cdot C_j) \right]_j + \sum_{k=1}^{N_r} \lambda_{k,j} \cdot \sigma_k; \quad j = 1, \dots, m \quad (52)$$

where t is time, and x is the position along the 1D spatial domain. The two terms in the square bracket are part of the transport operator (T) whereas the last term is the sum of all transformation processes. j is a particular species and C_j is the concentration of that species. ξ , v and D are variables that depends on the environmental system. σ_k represents the rate of the k -th kinetic reaction and $\lambda_{k,j}$ is the stoichiometric coefficient of species.

Although the critical zone is the fragile skin of the earth, the role of groundwater is an important factor that sustains the flora and fauna. If the groundwater table is raised, then it causes an increase in soil moisture and evapotranspiration, and further affects regional climate in the long term. Climate models without surface water–groundwater interactions tried to assess the interaction between climate–soil vegetation dynamics. The results show that vegetation properties can alter groundwater table dynamics (Leung et al. 2011). Numerical models are also utilized to understand surface water–groundwater interaction. MODFLOW's streamflow equations are utilized to assess the connectivity between surface and groundwater (Brunner et al. 2010). The exchange of volumetric flux between the surface water and groundwater is estimated by

$$Q_{SG} = \frac{K_c L w}{h_c} (h_{riv} - h) = c_{riv} (h_{riv} - h) \quad (53)$$

where K_c is the hydraulic conductivity of the clogging layer, L is the length of the river within a cell, w is the width of the river, h_c [L] is the thickness of the clogging layer, h_{riv} is the hydraulic head of the river, h is the groundwater head, and c_{riv} is the conductance of the clogging layer (McDonald and Harbaugh 1988).

Critical zone science has brought new opportunities and challenges for quantitative geomorphologists. Understanding the feedback mechanism between different processes using large datasets requires mathematical models. Handling multiple datasets from various sources and assimilation in a single generic modeling framework is complex. It is expected that the assimilation of large datasets with mathematical modeling will yield new insight into process interactions.

Conclusions

Individual geomorphic agent-based processes responsible for landscape evolution have been studied for several decades in the early twentieth century. Although these studies developed process-based understanding, the recent research queries are advancing to integrate the processes at different scales across different landforms or components. Quantitative geomorphology deals with this integration of different physiochemical processes to elucidate the landscape dynamics in a more holistic way. With the advent of large field data from different processes, comparison of model output with the real-world scenario is now easier to achieve. Furthermore, an interdisciplinary approach has brought several physics-based and mathematical tools to understand the geomorphic system. The use of coupled differential equations (ODE and PDE), statistical techniques, and many mathematical tools has helped to better explain the geomorphologic processes at different spatial and temporal scales. Furthermore, the use of long-term LEMs helps to assess the relative contribution of different geomorphic, tectonic, and climatic agents. Such quantitative approaches also help to integrate functional and evolutionary branches of geomorphology.

Quantitative geomorphology offers several approaches to derive indexes of relevance to geometry, topology, and morphology of terrestrial surfaces. Such indices would be of immense use in developing parameter-specific models through which one can make predictions of the dynamical behavior of the terrestrial surfaces. What is more interesting is to develop approaches to construct "geomorphologic attractors" that eventually provide short- and long-term behavioral predictions.

Quantitative Stratigraphy

Felix Gradstein¹ and Frits Agterberg²

¹University of Oslo, Oslo, Norway

²Central Canada Division, Geomathematics Section, Geological Survey of Canada, Ottawa, ON, Canada

Quantitative stratigraphy uses relatively simple or complex mathematical-statistical methods to calculate stratigraphic models that with a minimum of data provide a maximum of predictive potency, and include formulation of confidence limits. (F. P. Agterberg 1990)

Definition

The RASC method for RAnking and SCaling of biostratigraphic events was developed by the authors and associates to calculate large zonations with estimates of uncertainty. The purpose of ranking is to create an optimum sequence of fossil events observed in many different wells or sections subject to stratigraphic inconsistencies in the direction of the arrow of time. These inconsistencies, which result in crossovers of lines of correlation between sections, are due to various sampling errors and other sources of uncertainty including reworking and misclassification. They can be resolved by statistical averaging combined with stratigraphic reasoning. Subsequent scaling of the events may be carried out by estimating intervals between successive events along a relative timescale. This results in the scaled optimum sequence. Either the ranked optimum sequence or the scaled optimum sequence may be used for biozonation. The observed positions in the sections of different biostratigraphic events can have different degrees of precision. These differences may be evaluated through analysis of variance. Other types of stratigraphic events including logmarkers can be integrated and incorporated with the biostratigraphic events. Stratigraphically, the (scaled) optimum sequence represents the average order in which events occur in a sedimentary basin. The latter is realistic for practical correlations of strata.

Introduction

The purpose of this contribution is to provide a succinct description of RASC using the geomathematical method outlined in Agterberg and Gradstein (1999) and the Cretaceous microfossil data set of Gradstein et al. (1999) for illustration. The Cretaceous data set contains 1753 records on occurrences of 517 stratigraphic microfossil events in 31 exploration wells, offshore Norway.

Quantitative stratigraphy is also concerned with the correlation of lithologies or logs in different wells or outcrop sections. The emphasis in this entry is on biostratigraphic correlation although lithologies with lithostratigraphic signals can be incorporated into quantitative methods such as RASC.

Modern biostratigraphy must cope with occurrence data (events) from hundreds of fossil taxa, in thousands of samples derived from many wells or sections in a sedimentary basin. New tools in stratigraphy, using quantitative methods, make it easier to objectively build zonations integrating different microfossil groups. In addition, individual sections may be tested for “stratigraphic normality.” A prime method is called RASC for RAnking and SCaling of fossil events, and subject of this study.

RAnking and SCaling is a probabilistic method, available with Version 20. The method uses fossil event order in wells

or outcrop sections to construct a most likely and average sequence of events. This optimal order is scaled in relative time using crossover frequencies of all event pairs. The method provides detailed stratigraphic error analysis, and several correlation options, the latter executed in the program called CASC. RASC with CASC operates on all wells simultaneously, is very fast, handles large and complex data sets, and is relatively insensitive to noise. Literature on the method is extensive, and there are many applications, particularly in petroleum basins (see later). Before we outline the method itself, we briefly deal with the properties of fossil data and the data input.

A paleontological record is the position of a fossil taxon in a rock sequence. The stratigraphic range of a fossil is a composite of all its records from oldest to youngest in a stratigraphic sense. The endpoints of this range are biostratigraphic events, which include the first occurrence and appearance in time and last occurrence or disappearance from the geologic record. *A biostratigraphic event is the presence of a taxon in its time context, derived from its position in a rock sequence.* The fossil events are the result of the continuing evolutionary trends of Life on Earth; they differ from physical events in that they are unique, nonrecurrent, and that their order is irreversible. Often, first and last occurrences of fossil taxa are relatively poorly defined records, based on few specimens in scattered samples. Particularly with time-wise scattered last occurrences, one may be suspicious that reworking has locally extended the record, a reason why it is useful to distinguish between last occurrence (LO), and last common or last consistent occurrence (LCO), where consistency refers to occurrence in consecutive samples in a well or outcrop section. The shortest spacing in relative time between successive fossil events is called resolution. The greater the probability that such events follow each other in time, the greater the likelihood that correlation of the event record models isochrons. Most industrial data sets make use of sets of LO and LCO events. In an attempt to increase resolution in basin stratigraphy, particularly when many sidewall cores in wells are available, up to five events may be recognized along the stratigraphic range of a fossil taxon. Such events include last stratigraphic occurrence “top” or LO event, last common or last consistent occurrence LCO event, last abundant occurrence LAO event, first common or consistent occurrence FCO event, and first occurrence FO event (Fig. 1). Unfortunately, such practice may not yield the desired increase in biostratigraphic resolution sought after, for reason of poor event traceability. Event traceability is illustrated in Fig. 2, where cumulative event distribution is plotted against the number of wells for seven exploration and Deep Sea Drilling Project data sets with different microfossil records studied by the senior author. The events stem from dinoflagellates, foraminifers, and relatively few miscellaneous microfossils. The curves are asymptotic, showing an inverse relation between event

distribution and the number of wells. None of the events occur in all wells; clearly, far fewer events occur in five or six wells than in one or two wells, and hence the cumulative frequency drops quite dramatically with a small increase in number of wells. Obviously, the majority of fossil events have poor traceability, which is true for most data sets, either from wells or from outcrops (Gradstein and Agterberg 1998). Microfossil groups with higher local species diversity, on average, have less event traceability. Data sets with above average traceability of events are those where one or more dedicated observers have spent above average time examining the fossil record, verifying taxonomic consistency between wells or outcrop sections, and searching for “missing” data. In general, routine examination of wells by consultants yields only half or much less of the taxa and events than may be detected with a slightly more dedicated approach. There are other reasons than lack of detail from analysis why event traceability is relatively low. For example, lateral variations in sedimentation rate change the diversity and relative abundance of taxa in coeval samples between wells, particularly if sampling is not exhaustive, as with well cuttings or sidewall cores. It is difficult to understand why fossil events might be locally missing. Since chances of detection depend on many factors, stratigraphical, mechanical, and statistical in nature (Fig. 3), increasing sampling and studying more than one microfossil group in detail is beneficial. Although not admitted or clarified, biostratigraphy relies almost as much on the absence, as on the presence of certain markers. This remark is particularly tailored to microfossils that generally are widespread and relatively abundant, and harbor stratigraphically useful events. Only if nonexistence of events is recognized in many well-sampled sections, may absences be construed as affirmative for stratigraphic interpretations. If few samples are available over long stratigraphic intervals, the chance to find long-ranging taxa considerably exceeds the chance to find short-ranging forms, unless the latter are abundant. In actual practice, so-called index fossils have a short stratigraphic range and generally are less common, hence easily escape detection, a reason why their absence should be used with caution (Fig. 4).

Data Selection, Run Parameters, and Unique Events

It will be obvious to the user of RASC that a set of wells or outcrop sections to be zoned should have maximal stratigraphic overlap between sections and be devoid of major breaks or disconformities, etc. Since RASC is a statistical method, it is desirable to have sufficient sections (usually 10 or more) and sufficient events for calculation. Hence, events to be zoned should occur in at least 4, 5, 6, 7, or more sections (threshold K_c), with event pairs obviously set

Quantitative Stratigraphy, Fig. 1 Events recognized along the stratigraphic range of a fossil taxon. Such events include last stratigraphic occurrence “top” or LO event, last common or last consistent occurrence LCO event, last abundant occurrence LAO event, first common or

consistent occurrence FCO event, and first occurrence FO event. Unfortunately, such practice may not yield the desired increase in biostratigraphic resolution sought after, for reason of poor event traceability. Event traceability is illustrated in Fig. 3

to occur in fewer sections, e.g., 3 (threshold Mc). Index fossils, occurring in fewer than threshold Kc sections, may be introduced in the Optimum Sequence by the Unique Event routine. After calculation of the Optimum Sequence, assigned unique events are looked up in the single or few wells/sections where they occur. Their Optimum Sequence position is determined from the position of their nearest (section) neighbors above and below, known in the calculated optimum sequence. In the Optimum Sequence, these Unique Events have two stars.

QSCreator

Bundled with the RASC Programme Version 20 comes a simple routine called QSCreator, where QS stands for Quantitative Stratigraphy. QSCreator makes it fast and easy to

generate the input data, for RASC, and also provides a printable file for input data curation. The basic input for RASC consists of a list of event names dictionary (max. 999 events per dictionary, with fossil names of max. 45 characters, incl. spacing) and a well data file consisting of multiple records of the events in all wells considered (max. 150 wells, but <50 often desirable for reason of “noise” control). Many RASC applications are based on data derived from exploratory wells, as in the example of this study. In each well, the events observed to occur in the samples are characterized by their depths. However, it should be kept in mind that the method can be applied equally well to stratigraphic events observed in land-based outcrop sections. A reminder: When generating the RASC input files with QSCreator, the master dictionary should be in numeric sort mode (not alphabetic sort mode).

Quantitative Stratigraphy, Fig. 2 Cumulative frequency of micro-fossil event occurrences versus number of wells for seven subsurface data sets in the North Sea, offshore Canada and Atlantic and Indian Oceans (simplified after Gradstein and Agterberg 1999). Note the poor

traceability, which is a property of many biological-paleontological events in nature, with all events occurring in at least one well or section, but few events occurring in many sections. This feature is important to arrive at suitable RASC runs

Ranking and Scaling

RASC is an acronym for ranking and scaling of biostratigraphic events. There have been three distinct RASC method development phases:

1. 1978–1985: Starting from an algorithm for ordering biostratigraphic events proposed by Hay (1972), the basic

concepts of RASC were introduced and applied initially to Cenozoic Foraminifera in offshore wells drilled along the northwestern Atlantic Margin (Gradstein and Agterberg 1982). Other applications and evaluations of the method include Doeven et al. (1982) and Harper (1984). Implementation of the method was in the form of a mainframe computer program (Agterberg and Nel 1982a, b). Methodology and applications are detailed in

Quantitative Stratigraphy,**Fig. 3** Reasons why taxa might, or might not, be observed, leading to incomplete sampling

Gradstein et al. (1985). Development of RASC was carried out at the Geological Survey of Canada in Ottawa and Dartmouth, Nova Scotia, as part of Project 148 of the International Geological Correlation Program – Evaluation and Development of Quantitative Stratigraphical Correlation Methods, 1976–1985.

2. 1986–1994: Minor modifications of the method were introduced (D'Iorio and Agterberg 1989), and implementation was in the form of programs for personal computers. Large new applications are in Williamson (1987) and Gradstein et al. (1994).
3. 1995–1998: Modifications of RASC with addition of variance analysis were introduced in Agterberg and Gradstein (1997a, b, 1999), Agterberg et al. (1985), and Gradstein and Agterberg (1998). Novel applications included Gradstein and Bäckström (1996), Whang and Zhou Di (1998), and Corbett et al. (2014). Microcomputer application with attractive color graphics output was being facilitated by the development of a user-friendly Windows version of RASC. A 2-D Graphic Chart Control module in RASC allows editing of the final results for publication. This stage of computer development was sponsored by Saga Petroleum, Norway. RASC has seen large-scale professional applications by oil companies including Unocal, Shell, Saga Petroleum, Arco, Chevron, British Petroleum, Norsk Hydro, British Gas, and consulting companies like Millennia, UK.
4. 1999–2013: Emphasis in later versions of RASC and CASC was on graphic representation of the results (with original code made available on the website of the Editor, *Computers & Geosciences*). Additional features of RASC included the modeling frequency distributions of depth differences between successive events in the scaled optimum sequence as bilateral gamma distributions (Agterberg et al. 2007).

Ranked Optimum Sequence

The concept of an optimum sequence based on ranking was originally introduced by Hay (1972). All relative frequencies by which events are observed to occur stratigraphically above or below other events are considered. In the original Hay-type optimum sequence, the events are ranked in such a way that those above others in the optimum sequence have higher frequencies of occurring above these others, and lower frequencies of occurring below them. This ranking is based on superpositional relationships between events. In general, there are three possible types of superpositional relationships for a pair of events co-occurring in the same section. An event can be observed to occur above or below another event, or the two events coexist in the same sample. This third type of relationship, which implies that the two events are observed to be coeval, is ignored when an original Hay-type optimum sequence is constructed. In the ranked optimum sequence, which is based on a larger number of sections using nannofossils, two events can be coeval on the average when one of them occurs exactly as many times above the other one as it occurs below it. If an event is observed above another event in some sections but below it in others, a stratigraphic inconsistency involving these two events is indicated. The purpose of constructing the “modified Hay” method of ranking is to resolve such inconsistencies. Lines of correlation connecting observed positions of events in sections show crossovers when there are inconsistencies.

The so-called crossover frequency is defined as follows. If two events (A and B) occur in n sections with A above B in $n(AB)$ sections, A below B in $n(BA)$ sections, and A with B in the same sample in $n(A-B)$ sections, then the crossover frequency of A with respect to B is $f(AB) = \{n(AB) + 0.5n(A-B)\}/n$. Two events that are coeval on average have a crossover frequency equal to 0.5. When an event occurs

Quantitative Stratigraphy, Fig. 4 Crossover of dinoflagellate event correlations in four wells that sampled Upper Jurassic strata in the Troll field, offshore Norway (Gradstein, unpublished)

above another event in all sections, the crossover frequency is one, indicating absence of inconsistency in the observed superpositional relationships.

In most applications of ranking to large data sets, it is not possible to construct an optimum sequence according to the criteria outlined above. Pairwise inconsistencies, in which one event occurs above another in some sections but below it in other sections, are not the only possible type of inconsistency in superpositional relationships between events. Consider the following possibility: An event labeled A occurs more frequently above event B than the other way around, B occurs more frequently above C, and C occurs more frequently above A. This is an inconsistency involving three events. When a three-event cycle of this type occurs in the data set, it is not possible to construct the original Hay-type optimum sequence. However, by means of searching with the help of a computer, it is possible to identify those groups of three events which are involved in three-event cycles, and to study their superpositional relationships in detail. In RASC, such three-event cycles, and cycles involving more than three events (see next paragraph), are identified one after another. When a three-event cycle is found, the superpositional relationship of the two events that have the smallest difference between frequencies of occurring above and below one other is ignored.

Successive application of this rule to all cycles involving three or more events eventually results in an optimum sequence. In reality, the situation may be more complex if more than three events may be involved in a single cycle. For example, if event A occurs more frequently above B, B above C, C above D, and D above A, the result is a four-event cycle, provided that A and C as well as B and D are coeval on the average. If the latter condition is not satisfied, the four-event cycle is not real, because then the four events considered contain at least one three-event cycle which would be identified as such. Similar considerations apply to cycles involving more than four events. In general, the frequency of occurrence of four-event cycles is much less than that of three-event cycles, and cycles with more than four events are even rarer. This method of ranking is called the modified Hay method. Stratigraphically, the optimum sequence represents the average order in which events occur in a basin; a special graph in RASC shows the maximum extent of a last occurrence (LO event) or the very first occurrence of FO events, together representing the average range of a fossil in relative time. The latter often is more useful and more realistic for correlation than the extreme end points of a fossil in relative time (see below under Correlation).

The modified Hay method is not the only method that can be used for ranking stratigraphic events. Before the modified Hay method is utilized in RASC, the following ranking method called Presorting is applied first. Every event is compared with all other events. If an event occurs more frequently above another event, it receives an additional score of 1; if it

occurs more frequently below the other event, its score is not increased; and if it is coeval on the average with another event, both event scores are increased by 0.5. After adjusting the score with the ratio between linked events and the total number of events, the events can be ranked according to the magnitudes of their total scores in order to obtain an optimum sequence. Ranking methods based on scores have drawbacks because scores for many pairs may be missing (but corrected with above ratio), and events near the top or base of an optimum sequence automatically receive a full score. The advantage of presorting is that, with little computational effort, it results in a preliminary ranking which is likely to provide a good, preliminary solution. In RASC, the presorting result is refined by means of the modified Hay method.

Scaled Optimum Sequence

Biostratigraphic zonation not only determines stratigraphic order of events, but also provides a measure of separation in relative or linear time. The purpose of scaling in RASC is to compute interevent distances which are intervals between successive events in the optimum sequence. It is logical that two events that are coeval on the average will be assigned zero interevent distance along this scale. Scaling of the optimum sequence makes use of the stratigraphic reasoning that pairs of events in the optimum sequence with higher crossover frequency are closer together in relative time. Lines of correlation connecting observed positions of events in sections show crossovers when there are inconsistencies in the relative order of the events from section to section. Interevent distances are computed from z values which, in turn, are calculated from the crossover frequencies by the "probit" transformation $z_{ij} = \Phi^{-1}(f_{ij})$ where i and j are indexes that represent two stratigraphic events, and F represents the cumulative frequency of the normal Gaussian distribution in standard form. The probit transformation is widely applied in biometrics although not commonly for the purpose of scaling. It can be approximated by the linear transformation $z_{ij}^* = 2.93(f_{ij} - 0.5)$. For example, $f_{ij} = 0.5$ yields $z_{ij} = z_{ij}^* = 0$; $f_{ij} = 0.9$ gives $z_{ij} = 1.28$ and $z_{ij}^* = 1.17$.

Every estimated interevent distance is the weighted average of a single direct distance estimate and $(n^* - 1)$ indirect distance estimates. The direct distance estimate is simply the z_{ij} -value of the two events considered. Usually, there are many more indirect distance estimates which are based on differences between z -values. Each difference $(z_{ik} - z_{jk})$ involves a third event with index k that occurs in the vicinity of i and j in the optimum sequence. An advantage of using a single linear scale is that, on the average, any difference involving a third event is equal to the direct estimate. The expected value mathematical expectation of a direct estimate and all indirect

estimates of an interevent distance is the same. Discrepancies observed in practice between direct and indirect estimates can be ascribed to small-sample fluctuations and their effects reduced by averaging. The final estimated interevent distance is a function of the distance between each of the two events and all other events in the sequence which are in the vicinity of the two events. Weighting is applied during the computation of the average of the n^* individual estimates in order to account for the fact that crossover frequencies based on many superpositional relationships are more precise than those based on few; during this weighting, it also is considered that, taken separately, indirect estimates of distance are less precise than direct estimates. Standard deviations of the final interevent distances can be computed as well (see Agterberg 1990 for mathematical equations). The ranked optimum sequence is the starting point for all calculations outlined in the preceding paragraphs. Usually, several of the computed interevent distances turn out to be negative. However, by adding successive interevent distances, it is possible to calculate a cumulative RASC distance for every event. This cumulative distance is measured from the first event in the optimum sequence which can be defined as origin. Both origin and scale of the axis along which the events are plotted can be changed arbitrarily, because this scale is relative. Using cumulative distances, every event obtains a fixed position along the scale, and consequently, all interevent distances between successive events become positive, even if, initially, one or more negative values had been obtained. This procedure is called reordering. If there are no negative values, the order of the events remains unchanged. If negative interevent distances are computed, the preceding scaling calculations are repeated using the order of events in the initial scaled optimum sequence as the input sequence instead of the original ranking solution. The entire scaling process is repeated several times and results in elimination or significant reduction of the appearance of negative interevent distances during the calculations before final reordering is applied on the basis of the cumulative RASC distances.

A recent addition to RASC involves calculation of the scaled optimum sequence using thickness scaling of the events, as observed in each well or outcrop section (Agterberg et al. 2007). Depth differences between successive events in the optimum sequence satisfy frequency distributions as modeled for three large Cenozoic microfossil data sets consisting of 30 wells in the North Sea Basin, 27 wells on the Labrador Shelf and Grand Banks, and 11 wells in the western Barents Sea. The shapes of the three frequency distributions satisfy bilateral gamma distributions with similar parameters. These distributions are fitted by the construction of straight lines on normal Q–Q plots of square root-transformed average-corrected depth differences. The gamma distribution model is approximately satisfied except for small negative and positive depth differences, which have

anomalous frequencies because of the discrete sampling method used in exploratory well-drilling to collect microfossils. It implies not only comparable average stratigraphic order of events, but also comparable average sedimentation rates in the three Cenozoic basins selected for study.

Dendrogram

Graphic representation of scaling the optimum sequence using calculated interfossil distances is in the format of a dendrogram (see Fig. 5 left below). In this graph, the interfossil/interevent distances are plotted along a horizontal scale. At the end of each line segment, a vertical line is drawn in the stratigraphically downward direction until it hits another line or the base line. Groups of events with short interfossil distances form clusters which can be assigned zonal names, being representative of interval zones. Although the unique events are shown in the dendrogram, interevent distances involving them are not plotted, because they are less precise than the interevent distances calculated by scaling. Although trivial, it might be mentioned that the scaled clusters are not the result of cluster analysis. Pairs of events in the optimum sequence with higher crossover frequency are closer together in relative time. Large interfossil distances likely represent break in the local sedimentary sequence.

Testing Stratigraphic Fidelity

An important task in RASC is to calculate how well the order of events in the individual wells or sections compares to that of the computed optimum sequence zonation, either ranked or scaled (Gradstein 1984).

The step model is the one of three methods in RASC to compare individual sections to the (scaled) optimum sequence which can be regarded as an average or “standard” based on all sections. The order of the stratigraphic events in a section that belong to those included in the optimum sequence is compared to their order in the optimum sequence in the following way. Each event is compared to all others. One penalty point is assigned when the order of two events in the section is not the same as in the order of these two events in the optimum sequence. Half a penalty point is assigned when two events are observed to be coeval. Consequently, an event that, in comparison with its neighbors, occurs much higher in a section than in the optimum sequence, e.g., due to reworking, will receive a relatively large number of penalty points, one for every event with which it is out of step in comparison to the optimum sequence. Similar considerations apply to an event that occurs stratigraphically too low in a section.

Quantitative Stratigraphy, Fig. 5 (right) Optimum sequence of Cretaceous events foraminifera, dinoflagellates, miscellaneous microfossils, and one physical log marker, offshore mid-Norway, using the Ranking and Scaling RASC method on 1753 records in 31 wells. The arrow of time is upward. The majority of events are last occurrences LO in relative time; LCO stands for Last Common or Last Consistent Occurrence. Each event occurs in at least 6 out of 31 wells, leaving 97 events. The display also shows the relative stratigraphic position of nine unique events. The optimum sequence is graphically tied to the scaled optimum sequence RASC zonation to the left, largely using the nominate zone markers.

(left) Scaling in relative time of the optimum sequence of Cretaceous events shown in Fig. 5 (right). The arrow of time is upward; the intervall distances are plotted on the relative scale to the left in dendrogram display format. Each event occurs in at least 7 of the 31 wells, leaving 72 events. Sixteen stratigraphically successive interval zones are recognized, middle Albian through late Maastrichtian in age. Large breaks at events 52, 84, 205, 255, and 137 indicate transitions between natural microfossil sequences; such breaks relate to hiatuses or facies changes, some of which are known from European sequence stratigraphy (Gradstein et al. 1999)

The penalty events scored for all events in a section can be added. The total number of penalty points of a section not only reflects how well the order of the events in the section resembles the optimum sequence but it also depends on the number of optimum sequence events occurring in the section.

This total can be normalized to make it independent of total numbers of events in section and optimum sequence.

Two more stratigraphic fidelity tests in RASC are (1) the bivariate scattergram display of (scaled) optimum sequence versus well with a notation if events are outside the expected

cluster and (2) normality testing. Details are in Agterberg and Gradstein (1999).

Cretaceous Biozonation, Offshore Mid-Norway

In this section, we outline a Cretaceous biozonation in the Norwegian Sea, offshore mid-Norway, using foraminifera, dinoflagellates, and some miscellaneous microfossil taxa. Rather than trying to create a zonation that maximizes stratigraphic resolution, and often is difficult to apply over a broader region, we prefer to outline zonal units that are easy to correlate regionally. Hence, use was made of the RASC method to erect a zonation for the Cretaceous, which also has helped to integrate dinoflagellate events in the shelly microfossil biozonation.

Initially, the data set for RASC comprised the multiple microfossil event record in 37 wells, mostly LO or LCO events of 550 foraminifers, some siliceous microfossils, and dinoflagellates, for a total of 1873 records. After several intermediate zonations, using RASC and its normality-testing function of the event record, five erratic events and seven wells with very low sampling quality (partly due to turbo-drilling) were deleted from the data. For example, the following fossil event records were deleted, as being far too high, or too low stratigraphically in wells, as determined from RASC stepmodel penalty points: *Globorotalites multiseptus* in 34/7-24s, *Endoceratium dettmaniae* in 35/3-4, *Gaudryina filiformis* in 6507/6-2, *Gyroidinoides beisseli* in 34/7-22, and *Hedbergella* sp. in 6607/5-1; several LO events for dinoflagellate cyst taxa were changed into LCO events. In addition, *Rhaphidodinium fucatum*, *Heterohelix globulosa*, *Caudammina ovuloides*, *Dorothia trochoides*, *Hedbergella* sp., *Dorocysta litotes*, *Xenascus ceratoides*, *Florentinia mantelli*, *F. deanei*, and *F. ferox* showed highly erratic occurrences through the wells, leading to deletion from the run data. From our own observations, it is clear that *Hedbergella*

sp. consistently occurs in the nominate upper Cenomanian-lower Turonian zone, but in the original well record that is not obvious. In most cases, reasons for the erratic stratigraphic positions are not clear.

Despite filtering out (removal) of “bad” data from the RASC runs, 21 cycles needed to be broken prior to zonation, where groups of 3 or more events had an unresolvable stratigraphic order. In our experience with datasets from a variety of regions over the world, with different microfossils, 21 (event cycles) is a low number. Inclusion of the 10 events that were deleted from the data set would have increased the number of cycles from 24 to 43, and the number of events with 6 or more stepmodel penalty points from 14 to 36; out of place (AAA events) events in the scattergrams also were higher, whereas the number of out of place events using the RASC normality test would have declined from 78 to 64, not a significant change, but possibly the result of a “more complete,” although not more precise, optimum sequence.

As mentioned, the few wells omitted from the RASC run suffer from poor data coverage. The remaining 31 wells harbor 519 events, with 1755 records. Table 1 provides a summary of data properties and RASC results. The number of events in the optimum sequence, with SD < ave SD, deals with the number of events that have a standard deviation below the average for the optimum sequence; the fact that 44 out of 72 optimum sequence events have a lower than average standard deviation is good. Stratigraphic coverage is relatively good, even when, as usual, only 98 out of 519 events occur in 6 or more wells, and only 72 events occur in 7 or more wells (Fig. 2). Cretaceous dinoflagellate cysts in particular show large taxonomic diversity, but limited traceability for many taxa.

The Cretaceous optimum sequence (Fig. 5, right) includes 98 events (“tops”), spanning Hauterivian through Maastrichtian strata. In addition, 9 events noted with ** occur in fewer than 7 wells but are inserted for the purpose of zonal definition and chronostratigraphic calibration. The

NUMBER OF NORMALITY TEST EVENTS SHOWN WITH * OR **	78
NUMBER OF AAAA EVENTS IN SCALING SCATTERGRAMS	20

events listed are average last occurrences (average “top”), unless otherwise indicated; LCO stands for last common or last consistent occurrence, and FCO means first common or first consistent occurrence (in an uphole sense).

The so-called “Range” of taxa in the optimum sequence, which is a measure of the number of sequence positions an event spans (= rank positions in Fig. 5, right), is always low, except for *Fromea* sp. 2 (5 rank positions), *Dinopteridium cladoideus* (6 rank positions), *Trithyrodinium reticulatum* (5 rank positions), *Gyroidina beisseli* (5 rank positions), *Chatangiella niiga* (5 rank positions), and *Chatangiella* sp. (10 rank positions). The last occurrence record for these taxa is not reliable for detailed correlations in the wells examined. The optimum sequence serves as a guide to the stratigraphic order in which events in wells are expected to occur; hence, it is both predictive and serves in high-resolution correlation, as outlined below.

Figure 5, left is the scaled optimum sequence for the Cretaceous in the 31 wells, with interfossil distance from crossover pairs of events; this preferred scaled optimum sequence contains 72 events. Over a dozen stratigraphically successive Norwegian Sea Foraminifera (NCF) interval zones stand out, middle Albian through Maastrichtian in age. Resolution is poor in the lowermost and uppermost parts of the scaled sequence and reflects lack of superpositional data, and condensation of “tops” in the uppermost and lowermost Cretaceous part of wells.

The zones are named after prominent foraminiferal taxa that are easily recognized in the wells and are relatively widespread. The zones are informal, and their description is bound to change with addition of more data, and further assessment of taxonomy. Some of the foraminiferal index taxa (*Trocholina*, *Blefusciwana*, *Globigerinelloides gyroidinaeformis*, *Hedbergella brittonensis*, *Marginotruncana coronata*, and *Dicarinella concavata*) are rare due to the high-latitude setting of the study region, or poor preservation of carbonate tests in the siliceous mudstones. As mentioned earlier, integration, using the RASC method, with dinoflagellate events, improves the applicability of both types of microfossils for regional biostratigraphy.

Chronostratigraphic assignments are tentative, hampered among others by the absence, or scarcity or keeled planktonic foraminifers, like *Rotalipora*, and the majority of *Dicarinella*, *Marginotruncana*, and *Globotruncana*. Zones of short stratigraphic duration, like the *Sigmoilina antiqua* Zone, assigned to lower Cenomanian may be difficult to observe in ditch cuttings, particularly when the lithology is sandy. There is ample room for improving the resolution of the lower and upper parts of the zonation, for example, in the condensed Hauterivian-Barremian, and hiatus riddled, Aptian-middle Albian sections, and in the thick, carbonate devoid strata of the inner Voering Basin, assigned to Campanian (Gradstein

et al. 1999). The latter represents a poorly sampled section, probably laid down on a deep marine, middle bathyal basin floor.

The scaled optimum sequence shows major breaks between several successive zones, including between the *una* and *schloenbachi* zones, *delrioensis* LCO and *brittonensis* zones, *Marginotruncana* and *polonica* zones, *bellii* and *dubia* zones, and particularly between *dubia* and *szajnochae* zones. The question, of what the meaning is of these large breaks, is best answered when we consider how RASC scaling operates. Scaling calculates the relative stratigraphic distance between successive events in the RASC optimum sequence. This relative distance is calculated from the frequency of crossover of all possible pairs of events in the optimum sequence over all wells. Hence, large distances between successive events, corresponding to the larger RASC zonal breaks indicated above, signify strongly diminished crossover between events that occur below and above the breaks. Reasons for these breaks thus must be thought in stratigraphic gaps, and paleoenvironmental changes that likely are connected to sequence stratigraphic changes.

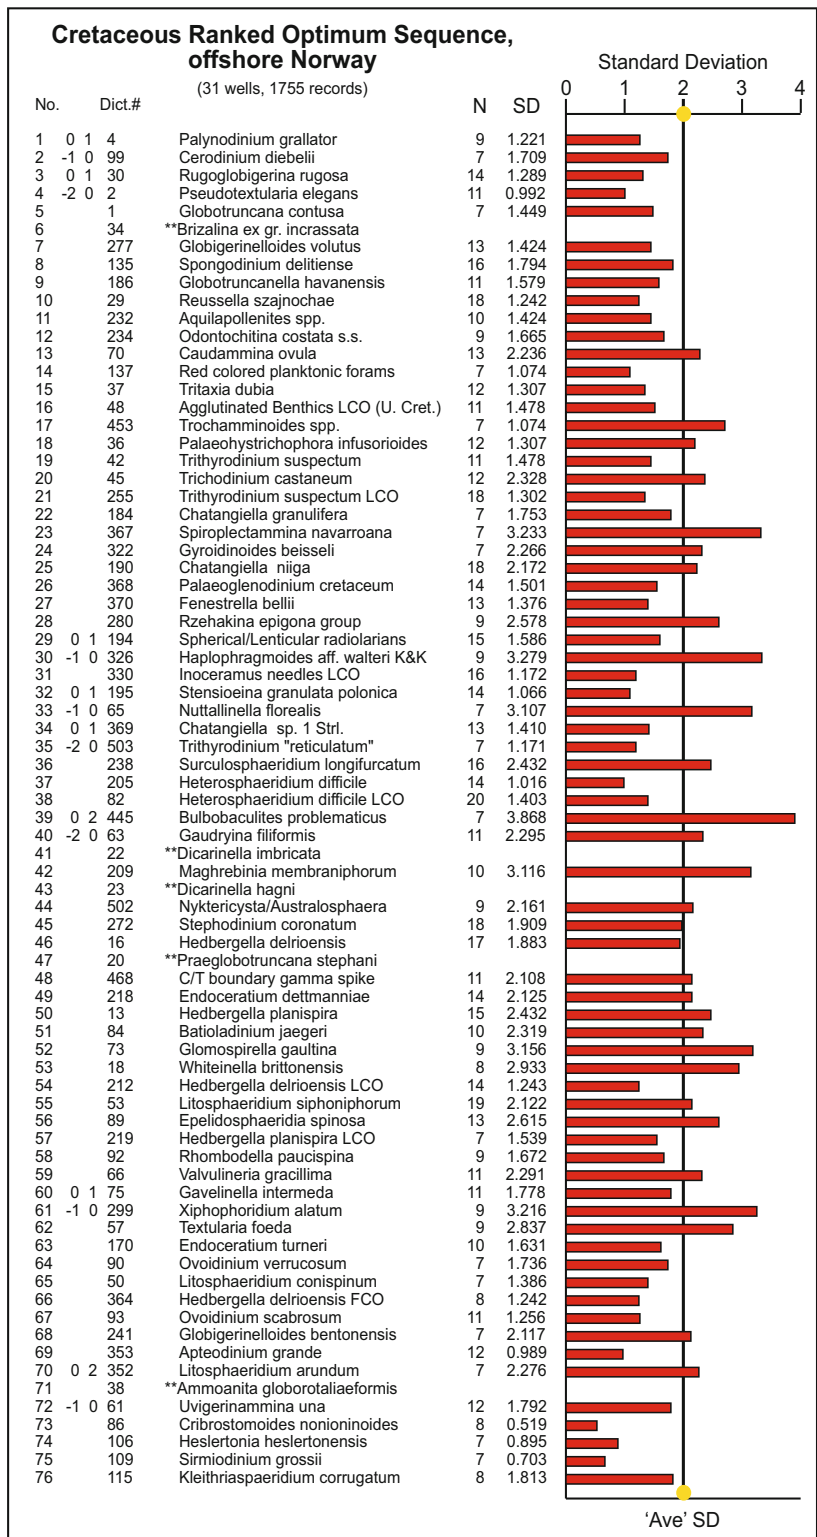

The reasons for this may be summarized as follows:

1. The *una-schloenbachi* break reflects a latest Albian lithofacies change and hiatus, connected to the Octeville hiatus in NW Europe.
2. The *delrioensis* LCO-*brittonensis* break reflects the mid-Cenomanian lithofacies change and hiatus, connected to the mid-Cenomanian nonsequence, and Rouen hardground.
3. The *Marginotruncana-polonica* break may be the turnaround in the tectono-eustatic phase of middle Coniacian, near the end of the Lysing sand deposition. The break occurs above the level of *Heterosphaeridium difficile* LCO, which represents a maximum flooding surface.
4. The *bellii-dubia* break occurs above the change from marly sediments to siliciclastic sediments that takes place in lowermost Campanian. The break, as the previous one, is near a maximum flooding event, i.e., the LCO of *T. suspectum* in the early middle Campanian.
5. The *dubia-szajnochae* break reflects the abrupt change from siliciclastic to marly sediment at the Campanian-Maastrichtian boundary, noted in the southern part of the region.

Within the major units, smaller zonal subdivisions may be recognized, using a combination of subjective judgment from individual well study, and objective subdivision from ranking and scaling analysis. Hence, the final zonation takes advantage of both subjective and more objective analysis and integrates the two into one framework.

Quantitative Stratigraphy,

Fig. 6 Summary of event variance analysis results for the Cretaceous optimum sequence of Fig. 5. To the left, the optimum sequence of Cretaceous microfossil events in 31 wells, offshore mid-Norway, where each event occurs in at least 7 out of 31 wells; N is the number of wells sampled to calculate the S.D. per event N, and S.D. is the standardized deviation from the line of correlation in each well. The average standard deviation of 1.8903 is the sum of all S.D.'s, divided by the total number of events in the optimum sequence. The asterisk behind events indicates an event with an S.D. that is smaller than the average S.D. From event S.D. theory, it follows that events with a below average S.D. correlate the same relative stratigraphic level more faithfully from well to well than events with a higher S.D.

**Correlation**

The complete RASC and CASC module executes automated stratigraphic correlation of wells or sections, using the (scaled) optimum sequence as zonal standard. However,

geologic correlation generally is a deterministic, and not a probabilistic process, using discrete tools like lithologic and/or log events and seismic markers with finite position in metric or travel time units.

Quantitative Stratigraphy,

Fig. 7 Correlation of events in the optimum sequence and zonation of Figs. 5 and 6 in Albian through Santonian strata in five wells, offshore mid-Norway. Green and red colored correlation lines are from events that have below average stratigraphic standard deviation, and are best track the same stratigraphic levels. Black lines are from events that have above average stratigraphic standard deviation and hence are less certain in correlation, and show some crossovers. Gravity flow sands are in yellow. The *Hedbergella delrioensis* FCO and LCO events (lower Cenomanian) and the *Inoceramus* LCO event (Santonian) are colored red and are considered flooding surfaces (FS). These events represent reliable regional correlation levels, with below average S.D. that reflect major marine transgressions, together with slow sedimentation. This graph clarified the localized and gravity flow nature of the sands, which could not be easily correlated using seismic and physical well logs stratigraphy

Automated correlation would not correct for events ending up on the wrong side of unconformities; it does not emphasize breaks between scaling clusters; it does not prevent events

from inadvertently ending up in gravity flow intervals; it does not provide weight to events with low variance; and it does not emphasize index fossil correlations, nor does it project

CASC correlations lines in an easy way on seismic or log correlation diagrams.

Having said so, there is an easy manner to operate reliable stratigraphic correlation through use of events with lower and higher stratigraphic fidelity from the optimum sequence with variance, like in Fig. 6 that shows correlation of events in Albian through Santonian strata in five wells, offshore mid-Norway (Fig. 7). Green and red colored correlation lines are from events that have below average stratigraphic standard deviation, and are best track the same stratigraphic levels. Black lines are from events that have above average stratigraphic standard deviation and hence are less certain in correlation, and show some crossovers. Gravity flow sands are in yellow. The *Hedbergella delrioensis* FCO and LCO events (lower Cenomanian) and the *Inoceramus* LCO event (Santonian) are colored red and are considered flooding surfaces (FS). These events represent reliable regional correlation levels, with below average S.D. that reflect major marine transgressions, together with slow sedimentation. This graph clarifies the local and gravity flow nature of the sands, which could not be easily correlated using seismic stratigraphy.

Conclusion

Although operation and execution of quantitative methods seemingly might appear to have a steep threshold and be difficult, the use of QSCreator for data input, rapid execution, and attractive graphic results, in reality, makes Ranking and Scaling (RASC) easy to use. Advantages may be summarized as follows:

1. Standardization of the fossil record and stratigraphic method gives easy access to data and results.
2. Data sets and results are easy to communicate and rapidly updated with new information.
3. Integration of all fossil and also physical (e.g., isotope, well-log) events in one stratigraphic solution increases resolution and practical use.
4. Methods and results (zonation + correlation) are more objective than handmade solutions.
5. Analysis of uncertainty in the event record and in the quantitative zonation greatly improves insight in true stratigraphic resolution and reliability of event correlation.
6. Interpolation of most likely (including missing) event positions in sections increases detail in correlation between sections.
7. Unlike subjective stratigraphy, the quantitative methods generally provide more than one possible solution, depending on run conditions, and provide biostratigraphy with multiple working hypotheses.

8. Quantitative stratigraphy methods can handle large and complex data sets, and calculate stratigraphic solutions fast and easy.

Quantitative Target Selection

Brandon Wilson¹, Emmanuel John M. Carranza² and Jeff B. Boisvert¹

¹University of Alberta, Edmonton, AB, Canada

²University of KwaZulu-Natal, Durban, South Africa

Definition

Determining an area of interest for mineral exploration involves risk and often has a low probability of success because economic ore deposits are rare. The main goal of early prospecting is mineral target selection – the identification of areas where targeted exploration and drilling should be pursued. Targets are defined as regions with favorable geology, anomalous geochemical concentrations, or other deposit-specific intrinsic characteristics that increase the probability of discovering a recoverable mineral resource.

Quantitative target selection is a data-driven process that identifies targets utilizing mathematical models fit to data from known mineral deposits using measured geological, geochemical, geophysical, and remotely sensed anomalies. Typical quantitative outputs include indicators of prospectivity or relative probability of mineralization. Conversely, qualitative target selection methods focus on using the understanding of ore formation processes to identify locations where the necessary conditions for mineralization exist.

Quantitative target selection models rely on the detection of multivariate signatures unique to specific mineral deposits of interest. These signatures can be directly fit to measured data in known mineralization locations using a variety of models. Alternatively, cutoff values can be applied to spatial models to represent the presence of ore and the probability of exceeding the cutoff value. Both methods can be used to generate prospectivity maps, which often display the relative probability of finding economic ore at a given location (Fig. 1).

The efficacy of quantitative target selection relies on analogous mineral deposits and available exploration data, which can be lacking depending on the area of interest. A combination of qualitative and quantitative target selection is preferred in practice, with qualitative methods used to limit the spatial extents in which quantitative models are

considered. In effect, quantitative methods are used to narrow down the results of a qualitative approach.

Motivation

Choosing exploration targets is often overlooked as a part of the mining cycle. Prospecting has become more difficult as a large proportion of outcropping deposits have been identified and exploited (Marjoribanks 2010). Additional sampling and predictive models are required to find new mineral deposits. Techniques for target selection vary between empirical and conceptual, while most practical implementations are a combination of both (Marjoribanks 2010). Conceptual methods focus on utilizing ore generation models and local geology to generate a relatively small number of high-probability ore targets.

In contrast, quantitative methods are used to associate measured variables with mineralized areas (Fig. 1). Measured geochemical, geophysical, mapping, and other data are related to known instances of mineralization using a variety of models. Data can be used to directly predict mineralization by assigning a binary variable to locations with known mineralization, followed by logistic regression or machine learning to predict ore likelihood in areas of interest (Carranza 2008; Xiong et al. 2018; Zuo 2020). Alternatively, data can be modeled to determine where critical genetic factors exist (Pan 2018). Critical genetic factors are geological processes that are necessary to generate concentrated ore. These factors are predicted through critical recognition criteria: combinations of variables meeting cutoffs that indicate the factor may be present (Pan 2018). Quantitative modeling predicts the probability that these criteria are met at a location of interest.

Before considering the construction of a mine, a selected target proceeds through a series of evaluation stages, including drilling, delineation, prefeasibility, and feasibility studies. Targets are eliminated from consideration at each evaluation stage, with only a small proportion proceeding because economic ore deposits are rare. Increasing the rate at which targets are converted to further exploration stages is the objective of target selection. Evaluating the success of target selection methods is difficult due to the random nature of mineralization and the sensitivity of evaluation metrics to the success or failure of single targets. A more robust but indirect measure of target selection success is the frequency of ore intersections found during early exploration drilling (Marjoribanks 2010); methods that identify locations where subsequent drilling more often pierces high grade mineralization are preferred, even if an ore deposit is not eventually found.

The goal of quantitative target selection is to generate an objective, data-driven measure of prospectivity to reduce subjectivity, increase reproducibility, and improve

Quantitative Target Selection, Fig. 1 Schematic of a typical quantitative target selection workflow and results. Concepts are labeled 1–7. 1) All available data is collected, transformed, interpolated, filtered, enhanced, etc. 2) Samples that are known to belong to deposit or non-deposit locations are split into training and testing sets and used in model development (steps 3, 4, 5). 3) Deposits are assessed for coherency, ensuring reliable detection and separation while reducing Type I errors.

4) A model type, such as logistic regression or random forest, is fit to coherent deposit data. 5) Model fit is assessed with training and testing data sets, facilitating model refinement if the fit is unacceptable (returning to steps 3, 4) or used as the final model if the fit is acceptable. 6) Data in locations with unknown mineralization are used in the fit model to predict prospectivity. 7) Outputs, such as prospectivity maps, are used to determine locations that are favorable for further exploration

consistency of target selection (Pan 2018); however, quantifying geological controls in a way that allows them to be effectively captured in a quantitative model is not trivial. Combining qualitative and quantitative methods is complementary and can improve model accuracy. Combined models include limiting quantitative model runs to areas determined to be appropriate by qualitative workflows.

Implementation

Many implementation decisions influence the quality of predictive models for target acquisition. These decisions include the size and location of the study area, defining positive and

negative examples of mineralization, and selection of data to use. For effective modeling, positive samples must share a multivariate data signature that is differentiable from background, non-mineralized locations. All deposits in a region that share such a signature are considered coherent (Fig. 1). An example that would confound most models follows: a set of known deposits are found to have elevated geochemical measurements with a measurable magnetic anomaly, but a subset of deposits does not present the anomaly – these sets of deposits are incoherent. Fitting a model to these samples would increase predicted false positives for deposits where the magnetic anomaly is necessary to indicate mineralization. To ensure deposit-type locations are coherent, Carranza et al. (2008) suggest logistic regression based on mineral

occurrence scores to classify deposits as coherent and non-coherent; a cutoff value splits the dataset, and only coherent deposit-type locations are used in modeling (Carranza et al. 2008).

Prediction scale is critical for quantitative target selection. Coarse grids limit the presence of outlying values necessary to detect a deposit due to the impacts of averaging data values. Conversely, fine grids are not reasonable where data is not correspondingly dense. It can be helpful to consider the probability of two deposit-type locations to be within a certain distance of each other; the maximum distance at which there is no probability of producing neighboring deposits is the maximum level of discretization that should be considered (Carranza 2008).

Numerous algorithms exist to fit and predict mineral occurrence scores or relative probabilities. Methods used as early as the 1980s include logistic regression, weights of evidence, and evidential belief functions. Since the 2000s, machine learning methods have increased in popularity as data availability and computing power improve, allowing for deeper models (Zuo 2020). Machine learning approaches that have been considered for quantitative target selection include neural networks, support vector machines, random forests, autoencoder networks, and convolutional neural networks (Zuo 2020).

Quantitative target selection workflows result in a variety of outputs. Typical deliverables include (1) mineral prospectivity maps (Fig. 1) showing relative potential to find deposits over a study area in the form of mineral prospectivity scores, and (2) relative target ranking, where specified target areas are prioritized by similar metrics (Pan 2018). Regardless of the specific type of output, the goal is to improve future exploration decisions.

Model validation is necessary to ensure that predictions are reliable and can be used to guide decision-making (Carranza 2008). Both model fit and predictive value must be considered and assessed with appropriate metrics. Fit metrics, such as r^2 , quantify how well the model represents the data it is modeling. Predictive metrics typically consider cross-validation techniques, such as k-fold validation, where data are left out and predicted with the proposed modeling workflow. The frequency of Type I and Type II errors and associated recall and precision values quantify: (1) how effectively ore locations are correctly identified as exploration targets, (2) how often they are missed, and (3) how often negative samples are mistakenly identified as targets. Validation can also take the form of splitting the data at locations with known levels of mineralization into training and testing sets and evaluating the efficacy of the model for predicting the test set (Carranza 2008). These metrics can be used to compare and choose between various models.

Data

Quantitative modeling is flexible in what types of data can be considered. Data can be continuous or discrete, exhaustively or sparsely sampled, measured or calculated, or even digitized qualitative data. Marjoribanks (2010) explores various types of geological data, including drilling, remote imagery, geochemical information, and geophysical variables. Many predictive models, such as logistic regression, require all data to be present at every evaluated location to produce a prediction. Many data sources, such as drillholes, are sparsely sampled and must be spatially interpolated (i.e., Kriging) or simulated (i.e., sequential Gaussian simulation) to be used as exhaustive inputs to quantitative target selection models. Transforming, filtering, and enhancing data are necessary preprocessing operations to develop a set of data appropriate for modeling and to maximize the value of information from data (Marjoribanks 2010; Pan 2018). Because geochemical anomalies are often critical to target identification, filters are applied to distinguish these extreme cases from background information. Care should be taken to ensure that issues such as smoothing and artifacts do not dilute data value (Pan 2018).

While there is an abundance of data types that can inform quantitative target selection, data availability is a significant limitation. Unexplored regions rarely have abundant, accessible, high quality data due to the expense of data collection and the remote nature of many prospective areas. However, many under-explored jurisdictions worldwide provide datasets to facilitate target selection, increase exploration investment, and encourage mining activities. Government agencies may publish regional target evaluations to incentivize exploration. For example, the Geological Survey of Canada provides mineral prospectivity maps on the Melville Peninsula in Nunavut (Harris et al. 2015). The quantitative data available in this region includes geochemical samples of lake sediment, airborne magnetic data, and gamma-ray spectrometer data. As the geochemical samples are discretely sampled, they are interpolated with Kriging to form a continuous data layer. A random-forest model is fit to predict the potential for gold mineralization based on 51 known occurrences, outperforming a knowledge-driven weighted index overlay model (Harris et al. 2015). The overall accuracy of the random-forest model is 85% based on 17 randomly selected gold occurrences. The data types used in this case study are commonly available for other regions in northern Canada.

The primary limitations to quantitative target selection are (1) a lack of available data, and (2) a lack of relevant known positive and negative examples of deposit-like locations required for model fitting. The same data types must exist in areas that are being evaluated, which often do not yet have

exploration-level drilling, leading to the prioritization of inexpensive remotely obtainable data. This can be particularly limiting for modeling methodologies that do not handle missing data during fitting, such as logistic regression and many machine learning algorithms (Carranza et al. 2008; Zuo 2020). Locations with missing data can be removed from consideration to fit the model. Alternatively, missing data can be simulated with imputation. Some machine learning methods, such as random forests, can be adapted to missing data to improve model flexibility (Zuo 2020).

Summary

Quantitative target selection is critical to managing risk associated with mineral exploration. Data is lacking during the early stages of exploration; therefore, reducing the number of targets considered while prioritizing high quality exploration targets optimizes capital expenditures and increases the conversion of targets to mineral reserves. The techniques employed to leverage existing data include mineral prospectivity analysis and machine learning approaches. Quantitative models alone may not be sufficient and combining them with qualitative methods improves results. Overall, quantitative target selection is a reasoned approach to increasing the conversion of exploration targets by leveraging all available data to decrease investment risk. The process has value for governments seeking investment and for companies seeking new targets.

Quaternions and Rotations

Helmut Schaeben

Technische Universität Bergakademie Freiberg, Freiberg, Germany

Definition

The skew field of real quaternions provides an extension of the system of numbers beyond complex numbers. Quaternions form a four-dimensional associative algebra $\mathbb{H}$ (associated with the name of Hamilton) over the field of real numbers $\mathbb{R}$. The components of a unit real quaternion can be related to the angle-axis parametrization of rotations. Expressing rotations in this way and applying quaternion multiplication simplify the concatenation of rotations and yield Rodrigues' formula providing the angle and axis of the resulting rotation in a straightforward manner.

Historical Note

At a time, mathematicians were pondering on two apparently unrelated problems. One problem pertained to the hierarchical number system of natural, integer, rational, real, and complex numbers $\mathbb{N}$, $\mathbb{Z}$, $\mathbb{Q}$, $\mathbb{R}$, and $\mathbb{C}$, and the open question whether a reasonable extension exists. Another problem concerned the concatenation, i.e., the sequential composition, of two rotations in three-dimensional Euclidean space $\mathbb{R}^3$ both given in terms of their angles and axes of rotation, i.e., $R(\omega, \mathbf{n}) = R_2(\omega_2, \mathbf{n}_2)R_1(\omega_1, \mathbf{n}_1)$ (to be read from right to left), and the question what the angle ω and the axis $\mathbf{n} \in \mathbb{S}^2$ of their concatenation are. The answer to both problems is provided by quaternions, more specifically the skew field of real quaternions $\mathbb{H}$. They are generally credited to Sir William Rowan Hamilton, who introduced the quaternion algebra with $i^2 = j^2 = k^2 = ijk = -1$ (Hamilton 1844) as carved in the stone of Broome Bridge of the Royal Canal. However, the resolution of the problem of concatenated rotations had been found earlier by Rodrigues (1840), who did not receive any

credit for his work on the special orthogonal group $SO(3)$ of rotations until recently (Altmann 1989). Gauss knew about quaternions since 1819, but his results remained unpublished until 1900 (Gauss 1900; Pujol 2012).

Yet another problem with rotations in $\mathbb{R}^3$ is the characterization of all rotations mapping a given unit vector $\mathbf{u} \in \mathbb{S}^2 \subset \mathbb{R}^3$ onto another given unit vector $\mathbf{v} \in \mathbb{S}^2$, i.e., $G(\mathbf{u}, \mathbf{v}) = \{R \in SO(3) | R\mathbf{u} = \mathbf{v}\}$. In terms of quaternions, this set of rotations is a great circle of the quaternion unit sphere $\mathbb{S}^3 \subset \mathbb{H}$ (Meister and Schaeben 2004), which in turn is a geodesic of $SO(3)$ (Novelia and O'Reilly 2015).

Rotations in $\mathbb{R}^2$ or $\mathbb{R}^3$

In Euclidean geometry, a rotation is a linear transformation that preserves distances. Thus a rotation is an isometry specified by its properties that it leaves at least one point fixed and that it preserves handedness. A rotation in two-dimensional Euclidean $\mathbb{R}^2$ is an isometry characterized by one fixed point and an invariant plane of rotation containing the fixed point; a rotation in three-dimensional Euclidean $\mathbb{R}^3$ is an isometry characterized by an axis of rotation, i.e., a line of its fixed points, and an invariant plane of rotation orthogonal to that axis. Then, rotations in $\mathbb{R}^3$ are determined by their angle $\omega \in (-\pi, \pi]$ and their axis of rotation $\mathbf{n} \in \mathbb{S}^2 \subset \mathbb{R}^3$. Rotations in $\mathbb{R}^2$ are determined by an angle of rotation $\omega \in (-\pi, \pi]$ referring to a two-dimensional plane spanned by orthonormal vectors $\mathbf{x}$ and $\mathbf{y}$ and a fixed point, usually the origin of the coordinate system provided by the unit vectors $\mathbf{x}$ and $\mathbf{y}$; thus, it may be thought of as rotation by $\omega \in (-\pi, \pi]$ about the axis $\mathbf{z}$ through the origin and orthogonal to vectors $\mathbf{x}$ and $\mathbf{y}$ spanning the invariant plane.

Rotations in $\mathbb{R}^n$, $n = 2, 3$, form the special orthogonal groups $SO(n)$, $n = 2, 3$, respectively, as they satisfy the following:

- Closure: For all $R_1, R_2 \in SO(n)$, the result of their concatenation, i.e., sequential composition R of first R_1 followed by R_2 , is an element of $SO(n)$, $R_2 R_1 = R \in SO(n)$.
- Associativity: For all $R_1, R_2, R_3 \in SO(n)$ it is $R_3(R_2 R_1) = (R_3 R_2)R_1$.
- Existence of an identity element: There exists an element $I \in SO(n)$ such that $IR = RI$ for every element $R \in SO(n)$.
- Existence of an inverse element: For each $R \in SO(n)$ exists an element $R^{-1} \in SO(n)$ such that $RR^{-1} = R^{-1}R = I$ where I is the identity element.

While the group $SO(2)$ is commutative, the group $SO(3)$ is not generally commutative as can be seen from the counter example

$$R_2(\pi/2, \mathbf{y})R_1(\pi/2, \mathbf{z})\mathbf{x} = R(\pi/2, \mathbf{y})\mathbf{y} = \mathbf{y}, \quad (1)$$

and

$$R_1(\pi/2, \mathbf{z})R_2(\pi/2, \mathbf{y})\mathbf{x} = R(\pi/2, \mathbf{z})(-\mathbf{z}) = -\mathbf{z}. \quad (2)$$

However, rotations in $\mathbb{R}^3$ about identical axes are commutative

$$R_2(\omega_2, \mathbf{n})R_1(\omega_1, \mathbf{n}) = R(\omega_1 + \omega_2, \mathbf{n}). \quad (3)$$

The Field $\mathbb{C}$ of Complex Numbers and Rotations in $\mathbb{R}^2$

A complex number $z \in \mathbb{C}$ is defined as

$$z = a + bi, i^2 = -1, \quad (4)$$

where a and $b \in \mathbb{R}$ are called a real and an imaginary part, respectively, and where i denotes the imaginary unit satisfying $i^2 = -1$. Complex numbers may be visualized as ordered pair $(\text{Re}(z), \text{Im}(z)) = (a, b)$ in the complex plane spanned by the basic units 1 and i , referred to as Argand diagram of complex numbers. The absolute value (modulus) and the argument (phase) of a complex number $z = a + bi$ are defined as

$$|z| = \sqrt{a^2 + b^2} = r, \quad \arg(z) = \theta. \quad (5)$$

The definition of the modulus implies the existence of an angle $\theta \in (-\pi, \pi]$ such that

$$a = r \cos \theta, \quad b = r \sin \theta, \quad (6)$$

and

$$z = r \cos \theta + ir \sin \theta = r(\cos \theta + i \sin \theta) = re^{i\theta}. \quad (7)$$

Especially for $r = 1$, it is

$$z = e^{i\theta}, \theta \in (-\pi, \pi], \quad (8)$$

carrying the visually inclined interpretation that a complex number z of modulus 1 varies along the unit circle in the complex plane centered at the origin as θ varies in $(-\pi, \pi]$, i.e., it is subject of a rotation by the angle θ about the axis $\mathbf{z} \in \mathbb{R}^3$ orthogonal to the complex plane through the origin of the coordinate system.

Multiplying $z_1 = \cos \theta_1 + i \sin \theta_1 = e^{i\theta_1}$, $z_2 = \cos \theta_2 + i \sin \theta_2 = e^{i\theta_2}$ results in

$$\begin{aligned} z_2 z_1 &= e^{i\theta_2} e^{i\theta_1} = e^{i(\theta_1 + \theta_2)} \\ &= \cos(\theta_1 + \theta_2) + i \sin(\theta_1 + \theta_2) \end{aligned} \quad (9)$$

reminiscent of the concatenation of two rotations $R_1(\theta_1, \mathbf{z})$ and $R_2(\theta_2, \mathbf{z})$ by angles θ_1 and θ_2 about the common axis of rotation $\mathbf{z} \in \mathbb{R}^3$, Eq. (3), leaving the complex plane invariant.

Real Quaternions Extending the Number System

A real quaternion $q \in \mathbb{H}$ is defined as

$$q = a + b_i + c_j + dk, \quad i^2 = j^2 = k^2 = ijk = -1, \quad (10)$$

where $a, b, c, d \in \mathbb{R}$ (Hamilton 1844). Then $a = \text{Sc}(q) = q_0$ is called scalar part, and $bi + cj + dk = \text{Vec}(q) = \mathbf{q}$ is called vector part of the real quaternion $q = q_0 + \mathbf{q}$. Hamilton's definition $i^2 = j^2 = k^2 = ijk = -1$ of the four basic units $1, i, j, k$, of real quaternions may be rewritten more instructively as a set of algebraic equations

$$(i) \quad i^2 = j^2 = k^2 = -1, \quad (11)$$

$$(ii) \quad ij = k, jk = i, ki = j, \quad (12)$$

$$(iii) \quad ij + ji = jk + kj = ik + ki = 0. \quad (13)$$

Real quaternions provide an extension of the hierarchical system of numbers beyond complex numbers.

If $\text{Sc}q = 0$, then q is called a pure quaternion; the subset of all pure quaternions is denoted $\text{Vec}\mathbb{H}$. For $q \in \text{Vec}\mathbb{H}$, q and $\mathbf{q}$ are identified, i.e., $q = \mathbf{q}$. The subset of all scalars may be denoted $\text{Sc}\mathbb{H}$. In this way, $\mathbb{R}$ and $\mathbb{R}^3$ are embedded in $\mathbb{H}$.

Given two quaternions, $p, q \in \mathbb{H}$, their quaternion product according to the algebraic rules, Eq. (11) above, is given by

$$pq = p_0q_0 - \mathbf{p} \cdot \mathbf{q} + p_0\mathbf{q} + q_0\mathbf{p} + \mathbf{p} \times \mathbf{q}, \quad (14)$$

where $\mathbf{p} \cdot \mathbf{q}$ and $\mathbf{p} \times \mathbf{q}$ represent the standard inner and cross product in $\mathbb{R}^3$; thus

$$\text{Sc}(pq) = p_0q_0 - \mathbf{p} \cdot \mathbf{q}, \quad (15)$$

$$\text{Vec}(pq) = p_0\mathbf{q} + q_0\mathbf{p} + \mathbf{p} \times \mathbf{q}. \quad (16)$$

Obviously, the quaternion product is not commutative.

The quaternion

$$q^* = \text{Sc}q - \text{Vec}q \quad (17)$$

is called the conjugate of q . With conjugated quaternions, it is possible to represent the scalar and vector part in an algebraic fashion as

$$q_0 = \text{Sc}q = \frac{1}{2}(q + q^*), \quad (18)$$

$$\mathbf{q} = \text{Vec}q = \frac{1}{2}(q - q^*). \quad (19)$$

It holds that

$$qq^* = q^*q = \|q\|^2 = q_0^2 + (q_1)^2 + (q_2)^2 + (q_3)^2, \quad (20)$$

and the number $\|q\|$ is called the norm of q . The norm of quaternions coincides with the Euclidean norm of q regarded as an element of the vector space $\mathbb{R}^4$. The scalar part of pq^* agrees with the usual Euclidean inner product in the space $\mathbb{R}^4$ and gives rise to the definition to the dot product of two real quaternions

$$p \cdot q = \text{Sc}(pq^*) = \sum_{i=0}^3 p_i q_i. \quad (21)$$

Since $(pq)^* = q^*p^*$, it is $\|pq\| = \|p\| \|q\|$. A quaternion q with $\|q\| = 1$ is called a unit quaternion. Furthermore, let $\mathbb{S}^2$ denote the unit sphere in $\text{Vec}\mathbb{H} \simeq \mathbb{R}^3$ of all unit vectors, and $\mathbb{S}^3$ the sphere in $\mathbb{H} \simeq \mathbb{R}^4$ of all unit quaternions. In complete analogy to $\mathbb{S}^2 \subset \mathbb{R}^3$, $\text{Sc}(pq^*) = p \cdot q$ provides a canonical measure for the spherical distance of unit quaternions $p, q \in \mathbb{S}^3$, i.e., the angle enclosed by p and q .

Each nonzero quaternion q has a unique inverse

$$q^{-1} = q^* / \|q\|^2 \quad (22)$$

with $\|q^{-1}\| = \|q\|^{-1}$. For unit quaternions, it is $q^{-1} = q^*$; for pure unit quaternions, it is $q^{-1} = -q$, implying $qq = -1$. The inverse of the unit quaternion $q = q_0 + \mathbf{q}$ is $q = q_0 - \mathbf{q}$.

Two quaternions p and $q \in \mathbb{H}$ are said to be orthogonal if pq^* is a pure quaternion, i.e., if $\text{Sc}(pq^*) = p \cdot q = 0$. According to Eq. (19), the condition of orthogonality may be rewritten as

$$2 \text{Sc}(pq^*) = pq^* + qp^* = 0. \quad (23)$$

If p and q are orthogonal unit quaternions, they are called orthonormal quaternions. It is emphasized that pure quaternions with orthogonal vector parts are orthogonal, but that the inverse is not generally true. Orthogonality of two quaternions does not imply orthogonality of their vector parts unless they are pure quaternions.

The Skew Field $\mathbb{H}$ of Real Quaternions and Rotations in $\mathbb{R}^3$

Any quaternion permits the representation

$$q = \|q\| \left(\frac{q_0}{\|q\|} + \frac{\mathbf{q}}{\|\mathbf{q}\|} \frac{\|q\|}{\|q\|} \right) \quad (24)$$

which implies the existence of an angle $\omega \in [0, \pi]$ such that

$$q = \|q\| \left(\cos \frac{\omega}{2} + \frac{\mathbf{q}}{\|\mathbf{q}\|} \sin \frac{\omega}{2} \right) \quad (25)$$

with $\omega = 2 \arccos(q_0/\|q\|)$, and $\|\mathbf{q}\|^2 = \mathbf{q}\mathbf{q}^*$ considering $\mathbf{q}$ as a pure quaternion. For an arbitrary unit quaternion, the representation Eq. (25) simplifies to

$$q = \cos \frac{\omega}{2} + \mathbf{n} \sin \frac{\omega}{2} \quad (26)$$

with the unit vector $\mathbf{n} = \mathbf{q}/\|\mathbf{q}\| \in \mathbb{S}^2$. The representation Eq. (26) suggests the association of a counterclockwise rotation in $\mathbb{R}^3$ by the angle ω about the axis $\mathbf{n} \in \mathbb{S}^2$. In fact, any rotation $R(\omega, \mathbf{n})$ by the angle $\omega \in [-\pi, \pi]$ about the axis $\mathbf{n} \in \mathbb{S}^2$ mapping the unit vector $\mathbf{u} \in \mathbb{S}^2$ onto the unit vector $\mathbf{v} \in \mathbb{S}^2$ according to

$$R(\omega, \mathbf{n})\mathbf{u} = \mathbf{v} \quad (27)$$

can be written in terms of the unit quaternion $q = \cos \frac{\omega}{2} + \mathbf{n} \sin \frac{\omega}{2}$ applying quaternion multiplication as

$$quq^* = \mathbf{v}, \quad (28)$$

where u and v are pure unit quaternions with vector parts $\mathbf{u}, \mathbf{v} \in \mathbb{S}^2$ and quaternion multiplication applies; for a proof, the reader is referred to (Downs 2003). Equation (28) reads explicitly

$$\mathbf{v} = \mathbf{u} \cos \omega + (\mathbf{n} \times \mathbf{u}) \sin \omega + (\mathbf{n} \cdot \mathbf{u})\mathbf{n}(1 - \cos \omega) \quad (29)$$

which is Rodrigues' formula for rotations in $\mathbb{R}^3$ (Rodrigues 1840). With $q^*vq = u$, the unit quaternion q^* provides the inverse rotation $R^{-1}(\omega, \mathbf{n})\mathbf{v} = R(\omega, -\mathbf{n})\mathbf{v} = \mathbf{u}$. Conjugation RR_0R^{-1} of a given rotation $R_0(\omega_0, \mathbf{n}_0)$ with an arbitrary rotation R is easily understood in terms of quaternions as the rotation

$$\begin{aligned} pq_0p^* &= p \left(\cos \frac{\omega_0}{2} + \mathbf{n}_0 \sin \frac{\omega_0}{2} \right) p^* \\ &= \cos \frac{\omega_0}{2} + p\mathbf{n}_0p^* \sin \frac{\omega_0}{2} \end{aligned} \quad (30)$$

about the rotated axes $p\mathbf{n}p^* \in \mathbb{S}^2$ by the same angle ω . Thus, conjugation may be applied to generate all rotations with a given angle of rotation.

Since the antipodal quaternions q and $-q$ yield the same rotation, the unit quaternion sphere $\mathbb{S}^4 \subset \mathbb{H}$ covers the special

orthogonal group $\text{SO}(3)$ twice. The association of rotations in $\mathbb{R}^3$ with unit quaternions in $\mathbb{S}^3$ implies the interpretation that the unit sphere of vectors $\mathbb{S}^2 \subset \mathbb{R}^3$ thought of as being embedded in $\text{Vec}\mathbb{H}$ is associated with all rotations by the angle π about arbitrary axes. Comprehensive expositions of real quaternions and their relationships to rotations in $\mathbb{R}^3$ are given in (Altmann 2013; Hanson 2006; Kuipers 1999).

Concatenation of Rotations

Let the rotations $R_1 = R_1(\omega_1, \mathbf{n}_1)$ and $R_2 = R_2(\omega_2, \mathbf{n}_2)$ be associated with unit quaternions

$$q = \cos \frac{\omega_1}{2} + \mathbf{n}_1 \sin \frac{\omega_1}{2} \quad (31)$$

$$p = \cos \frac{\omega_2}{2} + \mathbf{n}_2 \sin \frac{\omega_2}{2}. \quad (32)$$

Then the concatenation $R = R(\omega, \mathbf{n}) = R_2(\omega_2, \mathbf{n}_2)R_1(\omega_1, \mathbf{n}_1)$ is associated with the product pq as defined in Eq. (14)

$$pq = p_0q_0 - \mathbf{p} \cdot \mathbf{q} + p_0\mathbf{q} + q_0\mathbf{p} + \mathbf{p} \times \mathbf{q}, \quad (33)$$

and its scalar and vector parts, respectively,

$$\cos \frac{\omega}{2} = \text{Sc}(pq) = p_0q_0 - \mathbf{p} \cdot \mathbf{q}, \quad (34)$$

$$\mathbf{n} \sin \frac{\omega}{2} = \text{Vec}(pq) = p_0\mathbf{q} + q_0\mathbf{p} + \mathbf{p} \times \mathbf{q} \quad (35)$$

provide the angle ω and the axis $\mathbf{n}$ of the rotation R . It resolved the historical quest for angle and axis of sequential compositions of rotations in terms of quaternions in a straightforward way. An Earth science application is presented in detail in the entry ► “Euler Poles of Tectonic Plates” of this Encyclopedia where the path of a migrating relative Euler pole given two absolute Euler poles is determined.

Geodesics

Let q_1 and $q_2 \in \mathbb{S}^3$ be two orthonormal quaternions. The set of quaternions

$$q(t) = q_1 \cos t + q_2 \sin t, \quad t \in (-\pi, \pi], \quad (36)$$

parametrizes the great circle denoted $C(q_1, q_2) \subset \mathbb{S}^3$ spanned by q_1 and q_2 . Obviously, $-q_1$ and $-q_2 \in \mathbb{S}^3$ define the same great circle $C(q_1, q_2)$. Any $q(t) \in C(q_1, q_2)$ satisfies (Meister and Schaeben 2004)

$$q(t)(q_1^*q_2)q^*(t) = q_2q_1^*, t \in (-\pi, \pi]. \quad (37)$$

Since q_1 and q_2 are orthonormal, $q_1^*q_2$ and $q_2q_1^*$ define pure unit quaternions $\mathbf{u} = q_1^*q_2$, $\mathbf{v} = q_2q_1^*$. For example,

$$\begin{aligned} q_1 &= \cos\left(\frac{\arccos \mathbf{u}\mathbf{v}}{2}\right) + \frac{\mathbf{u} \times \mathbf{v}}{\|\mathbf{u} \times \mathbf{v}\|} \sin\left(\frac{\arccos \mathbf{u}\mathbf{v}}{2}\right) \\ &= \frac{1 - \mathbf{v}\mathbf{u}}{\|1 - \mathbf{v}\mathbf{u}\|} \end{aligned} \quad (38)$$

$$q_2 = \frac{\mathbf{u} + \mathbf{v}}{\|\mathbf{u} + \mathbf{v}\|} = \frac{u + v}{\|u + v\|} \quad (39)$$

for $\mathbf{u}, \mathbf{v} \in \mathbb{S}^2$ with $\mathbf{v} \neq -\mathbf{u}$.

The fiber $G(\mathbf{u}, \mathbf{v}) \subset \text{SO}(3)$ of all rotations R with $R\mathbf{u} = \mathbf{v}$ is associated with the great circle $C(q_1, q_2) \subset \mathbb{S}^3 \subset \mathbb{H}$ spanned by unit quaternions $q_1, q_2 \in \mathbb{S}^3$ given in terms of $\mathbf{u}, \mathbf{v} \in \mathbb{S}^2$ by Eqs. (38) and (39), for example. Since $q(t)$ and $-q(t)$ are associated with the same rotation, the circle $C(q_1, q_2)$ covers the fiber $G(\mathbf{u}, \mathbf{v})$ twice. The fibers $G(\mathbf{u}, \mathbf{v}), (\mathbf{u}, \mathbf{v}) \in \mathbb{S}^2 \times \mathbb{S}^2$ induce a double fibration or double covering of $\text{SO}(3)$ as

$$\bigcup_{\mathbf{u} \in \mathbb{S}^2} G(\mathbf{u}, \mathbf{v}) = \bigcup_{\mathbf{v} \in \mathbb{S}^2} G(\mathbf{u}, \mathbf{v}) = \text{SO}(3) \quad (40)$$

for any fixed $\mathbf{u}$ or fixed $\mathbf{v}$, respectively. In the same way, the great circles, $C_{\mathbf{u}, \mathbf{v}} \subset \mathbb{S}^3$, induce a double fibration of $\mathbb{S}^3$.

A major property of the great circle $C(q_1, q_2) \equiv C_{\mathbf{u}, \mathbf{v}}$ is that it can be parametrized by a pair $(\mathbf{u}, \mathbf{v}) \in \mathbb{S}^2 \times \mathbb{S}^2$ and its antipodally symmetric $(-\mathbf{u}, -\mathbf{v})$ in the way that it consists of all quaternions $q(t), t \in (-\pi, \pi]$, with $q(t)\mathbf{u}q^*(t) = \mathbf{v}$ for all $t \in (-\pi, \pi]$, and that it covers the fiber $G(\mathbf{u}, \mathbf{v})$ twice. While it is obvious that great circles $C(q_1, q_2)$ of $\mathbb{S}^3$ are its geodesics, their parametrization $C_{\mathbf{u}, \mathbf{v}}$ in terms of two unit vectors $\mathbf{u}$ and $\mathbf{v}$ such that the great circle corresponds to the fiber $G(\mathbf{u}, \mathbf{v}) \subset \text{SO}(3)$ of all rotations mapping $\mathbf{u}$ onto $\mathbf{v}$ reveals that the fibers are the geodesics of $\text{SO}(3)$. In fact, they are actually Hopf fibers.

Replacing $\mathbf{u}$ by $-\mathbf{u}$ in Eqs. (38) and (39) yields

$$\begin{aligned} q_3 &= \cos\left(\frac{\arccos(-\mathbf{u}\mathbf{v})}{2}\right) \\ &\quad + \frac{-\mathbf{u} \times \mathbf{v}}{\|-\mathbf{u} \times \mathbf{v}\|} \sin\left(\frac{\arccos(-\mathbf{u}\mathbf{v})}{2}\right) \\ &= \frac{1 + \mathbf{v}\mathbf{u}}{\|1 + \mathbf{v}\mathbf{u}\|} \end{aligned} \quad (41)$$

$$q_4 = \frac{-\mathbf{u} + \mathbf{v}}{\|-\mathbf{u} + \mathbf{v}\|} = \frac{-u + v}{\|-u + v\|} \quad (42)$$

and results in four mutually orthonormal quaternions $q_1, \dots, q_4$. Thus, the two circles $C(q_1, q_2)$ and $C(q_3, q_4)$ associated with the two fibers $G(\mathbf{u}, \mathbf{v})$ and $G(-\mathbf{u}, \mathbf{v})$, respectively, are

orthonormal to one another. Integration of suitable functions along geodesics gives rise to their Funk or Radon transforms, respectively. The Funk-Radon transform of an orientation probability density function defined on $\mathbb{S}^3$ provides the basic model of integral orientation measurements with X-ray or Neutron diffraction as applied in the analysis of “Crystallographic Preferred Orientation” (this Encyclopedia).

Conclusions

“Spoiler alert: unit quaternions provide ‘the’ way to represent rotations. Why? Unit quaternions allow a clear visualization (see Hanson 2006) of the space of rotations as the unit sphere $\mathbb{S}^3$ in four dimensions (with antipodal points identified). Unit quaternions make it possible to differentiate an expression ‘with respect to rotation’. Unit quaternions make it possible to find extrema of expressions by setting that derivative equal to zero! Unit quaternions make it easy to compose rotations (unlike, e.g., axis- and-angle notation). Unit quaternions do not suffer from singularities (as do, e.g., Euler angles when two axes line up see gimbal lock). Unit quaternions, while redundant (four parameters for three degrees of freedom), have only one constraint on their components (unlike orthonormal matrices, which have six non-linear constraints on the rows or columns plus one on the determinant). Unit quaternions make it possible to compute averages, to interpolate, to sample in the space of rotations and to represent densities over orientations. And, as demonstrated in Andrew Hansons (2020) article in the previous issue of Acta Crystallographica Section A, they also make possible insightful illustrations relating to orientations.” (Horn 2020)

Radial Basis Functions

Michael Hillier

Geological Survey of Canada, Ottawa, ON, Canada

Definition

Radial Basis Functions (RBFs) are used for scattered data approximation, a numerical method for approximating an unknown function $f(\mathbf{x})$ with an interpolant $s(\mathbf{x})$ from a distinct set of N sampled scattered data points $X = \{\mathbf{x}_1, \dots, \mathbf{x}_N\} \subseteq \mathbb{R}^d$ having data values $f(\mathbf{x}_j)$, $1 \leq j \leq N$. RBF interpolants provide optimal approximation of $f(\mathbf{x})$ and can be computed efficiently using RBF-based optimizations for domain decomposition, fast matrix solvers, and interpolant evaluators. In geoscience, RBF interpolation emerged as a useful method to rapidly compute geological features for various applications. RBF interpolants are expressed in terms of linear combinations of radially symmetric kernel functions of the form $\Phi(\mathbf{x}, \mathbf{x}_j) := \phi(r)$ centered on data point $\mathbf{x}_j$ where $r = \|\mathbf{x} - \mathbf{x}_j\|_2$ is the Euclidean distance between two points. These interpolants have the form

$$s(\mathbf{x}) = \sum_{j=1}^N w_j \Phi(\mathbf{x}, \mathbf{x}_j) + p(\mathbf{x}) \quad (1)$$

where $p(\mathbf{x})$ is a l -degree d -variate polynomial

$$p(\mathbf{x}) = \sum_k^Q c_k p_k(\mathbf{x}), Q = \frac{(l+d)!}{l!d!} \quad (2)$$

Coefficients w_j and c_k are determined from the linear system

$$\begin{bmatrix} A & P \\ P^T & 0 \end{bmatrix} \begin{bmatrix} \mathbf{w} \\ \mathbf{c} \end{bmatrix} = \begin{bmatrix} \mathbf{f} \\ 0 \end{bmatrix} \quad (3)$$

where $A = \Phi(\mathbf{x}_j, \mathbf{x}_k) \in \mathbb{R}^{N \times N}$ and $P = p_k(\mathbf{x}_j) \in \mathbb{R}^{N \times Q}$ is linearly independent and generated from the interpolation conditions $s(\mathbf{x}_j) = f(\mathbf{x}_j)$, $1 \leq j \leq N$. The block matrix on the left-hand side of Eq. 3 is referred to as the interpolation matrix. Optimal RBF interpolants providing the smoothest possible interpolation and minimal pointwise error are guaranteed from the solution of Eq. 3 when A is positive definite, defined by $\mathbf{w}^T A \mathbf{w} > 0$. RBFs can be split into two categories: strictly positive definite (SPD) and conditionally positive definite (CPD). Commonly used SPD and CPD RBFs are listed in Tables 1 and 2, respectively. Refer to Wendland (2005) for detailed analysis and properties of these functions. For SPD RBFs, A is always positive definite, whereas conditionally positive definite (CPD) RBFs of order m require the orthogonality constraints

$$\sum_j^N w_j p_k(\mathbf{x}_j) = 0, \quad 1 \leq k \leq Q \quad (4)$$

to ensure positive definiteness where $p(\mathbf{x})$ is at most a $(m-1)$ -degree polynomial. Furthermore, for SPD RBFs, low-degree polynomials are not required however can be useful for extrapolation. Notations used in this definition are given in Table 3.

Introduction

Scattered data approximation methods utilizing radial basis functions originally appeared in spatially dependent geoscience applications such as geodesy, hydrology, and geophysics in the early 1970s. A thorough review on these early works, using multiquadric and inverse multiquadric RBFs, is found in Hardy (1990). Beyond the 1980s, a myriad of uses for RBFs were found in a wide range of applications including artificial intelligence, solving PDEs, optimization, finance, signal processing, and 3D modeling. Their success can be

Radial Basis Functions, Table 1 Common SPD RBFs

Strictly positive definite (SPD) RBF	$\phi(r)$
Gaussian	$e^{-(\varepsilon r)^2}$
Inverse multiquadric	$(\varepsilon^2 + r^2)^{k/2} \quad k < 0$
Wendland (C^2)	$(1 - r_c)^4(4r_c + 1), r_c < 1$ $0, r_c \geq 1$
Wendland (C^4)	$(1 - r_c)^6(35r_c^2 + 18r_c + 3), r_c < 1$ $0, r_c \geq 1$
Matérn (C^0)	$e^{-\varepsilon r}$
Matérn (C^2)	$e^{-\varepsilon r}(1 + \varepsilon r)$
Matérn (C^4)	$e^{-\varepsilon r}(3 + 3\varepsilon r + (\varepsilon r)^2)$

Smaller shape parameters ε correspond to flatter functions as r increases. For Wendland's functions, the variable $r_c = r/R$ where R is a cutoff radius. For values $r_c > 1$, the function is zero

Radial Basis Functions, Table 2 Common CPD RBFs and their conditional order m

Conditionally positive definite (CPD) RBF	$\phi(r)$	Conditional order m
Multiquadric	$(\varepsilon^2 + r^2)^{k/2} \quad k > 0, k \notin 2\mathbb{N}$	$\lceil k/2 \rceil$
Radial powers	$r^k \quad k > 0, k \notin 2\mathbb{N}$	$\lceil k/2 \rceil$
Thin-plate splines	$r^{2k} \log r \quad k > 0, k \in \mathbb{N}$	$k + 1$

Radial powers and thin-plate splines are known as polyharmonic splines

Radial Basis Functions, Table 3 Notations and associated descriptions used in the RBF definition

Notations	Descriptions
d	Dimensionality
$\mathbf{x}$	d -dimensional point, e.g., 3D point $\mathbf{x} = (x, y, z)$
X	Set of scattered points $\{\mathbf{x}_1, \dots, \mathbf{x}_N\}$. Scattered points are irregularly distributed
N	Number of data points in point set X
$\mathbf{x}_j$	j -th data point from X
$f(\mathbf{x})$	Unknown scalar value at point $\mathbf{x}$
$s(\mathbf{x})$	Interpolated scalar value at point $\mathbf{x}$
$\Phi(\mathbf{x}, \mathbf{x}_j)$	Kernel function. Two points ($\mathbf{x}$ and $\mathbf{x}_j$) are input, and output is a scalar
r	Euclidean distance between two points
$\phi(r)$	Radial basis function
l	Degree of polynomial
$p(\mathbf{x})$	l -degree polynomial, e.g., 1-degree trivariate (3D): $p(\mathbf{x}) = c_1x + c_2y + c_3z + c_4$
$p_k(\mathbf{x})$	k -th monomial of polynomial, e.g., 1-degree trivariate polynomial has 4 monomials: $(x, y, z, 1)$, 2-degree trivariate polynomial has 10 monomials: $(x^2, y^2, z^2, xy, xz, yz, x, y, z, 1)$
Q	Number of monomials for polynomial
$\mathbf{w}$	RBF coefficients $\mathbf{w} = (w_1, \dots, w_N)$
$\mathbf{c}$	Polynomial coefficients $\mathbf{c} = (c_1, \dots, c_Q)$
A	Symmetric kernel matrix generated by radial kernel $\Phi(\mathbf{x}, \mathbf{x}_j)$ using all of point pairs of point set X
P	Polynomial matrix containing all monomials for point set X
$\mathbf{w}^T A \mathbf{w}$	Quadratic form associated with A . Interpolant smoothness is measured in terms of the quadratic form: $\ s\ ^2 = \mathbf{w}^T A \mathbf{w}$, where $\ s\ $ is the interpolant's norm. Positive definiteness of the quadratic form (e.g., $\mathbf{w}^T A \mathbf{w} > 0$) ensures the smoothest possible interpolation
m	Conditional order of CPD RBF
ε	SPD RBF shape parameter
R	Cutoff radius for Wendland's RBFs
r_c	Wendland's RBF variable

attributed to the robustness, versatility, and simplicity of the mathematical models that use them.

Important historical milestones beyond Hardy's pioneering work will be given. The variational approach

developed by Duchon (1976) demonstrated that polyharmonic splines, like thin plate splines, minimize the bending energy (e.g., aggregated squared curvature). These characteristics enabled modeling of complex surface

geometries with arbitrary genus topology in addition to desirable surface smoothness and hole-filling properties. In the mid-1980s, Micchelli (1986) proved the interpolation matrix is always invertible and laid a strong foundation for future work. By the late 1990s and early 2000s, these theoretical foundations coupled with dramatic increases in computing power, and RBF-based optimization techniques led to widespread use of implicit modeling of complex 3D objects from large datasets (Carr et al. 2001). The most common use of RBFs in geoscience is with implicit modeling.

Interestingly, the geostatistical method of interpolation known as kriging which takes a stochastic point of view of data observations as realizations of random variables belonging to a random field has been proven mathematically equivalent to RBF interpolation (Dubrule 1984; Scheuerer et al. 2013). Although these connections have been known by geostatisticians for some time, it has been only recently recognized by the numerical analysis community. RBF interpolation can be viewed as a subset of kriging with a chosen fixed covariance function and polynomial trend degree. In kriging, covariance functions are estimated from data.

RBF Implicit Modeling

Implicit modeling is a method by which iso-contours implicitly defined as some level set of a reconstructed scalar function are extracted from a discretized domain (e.g., triangulated meshes, voxel grids). Iso-contours, such as curves (2D) and surfaces (3D), require interpolants to be first evaluated throughout the discretized domain. Iso-contour extraction from evaluated domains is performed using computer graphic algorithms such as marching cubes (Lorensen and Cline 1987) (for 3D applications).

In geoscience, RBF-based implicit modeling methods are routinely applied to geologically derived structures and properties (Cowan et al. 2002) and provide a fast, automatic, and reproducible approach. Figure 1 illustrates RBF implicit modeling for 3D structural geology and ore grade estimation applications. Information regarding geological setting and data used for these examples can be found in de Kemp et al. 2016. Implicit modeling greatly improved upon shortcomings of previously widely used approaches for these applications called explicit modeling. Explicit-based modeling approaches required manual wireframe construction by Bezier and NURB objects by a modeler using CAD tools. Although explicit modeling offered great precision and flexibility, they suffered from lengthy nonreproducible user-dependent wireframe creation, as well as being difficult to update to newly acquired data – a common occurrence in geoscience.

Many geoscience applications suffer from limited data observations and give rise to nonunique models. There are an infinite set of solutions describing given observations. In

underdetermined settings, domain experts would like to test possible scenarios and hypotheses explaining physical phenomena apparent from data observations. Implicit modeling provides a framework in which many of these scenarios can be quickly tested and compared. Furthermore, recent developments in implicit model uncertainty characterization using Bayesian inference can quantify the degree to which scenarios are more likely (de la Varga and Wellmann 2016). These considerations make implicit modeling particularly advantageous in geoscience applications.

For structural RBF implicit modeling, geologically derived surfaces, such as interfaces between stratigraphic layers, are commonly implicitly defined as the zero-level set of the reconstructed scalar function (e.g., $f(\mathbf{x}) = 0$). In order to obtain nontrivial solutions to Eq. 3, additional points, called offset points, are generated by projecting known surface points attributed with planar orientation (e.g., normal), either measured or derived. Constraints for scalar values of offset points are set to its projection distance. Offset points above the surface distances are positive, whereas points below distances are negative. Geometrical artifacts in modeled surfaces using offset points can occur when modeling highly variant structures, since depending on the chosen projection distance points can be projected on the wrong side of the surface. Structural field observation datasets predominantly contain orientation measurements not directly sampling the surface of interest. Since off-surface orientation measurements influence the surface of interest's geometry, with closer measurements having greater impact than further measurements, the offset point approach to implicit modeling for such applications is far from optimal. Problems arising from the offset points were resolved by extensions to the basic RBF interpolation method explained in the next section.

RBF Methods and Enhancements for Geoscience

RBF interpolants of the form Eq. 1 can be expanded to include derivatives, inequality, surface points from multiple distinct surfaces, and fault constraints further enhancing modeling capacity for geoscience applications. Supplementary to the additional constraints, important RBF-based approximation methods will be described that may provide helpful for noisy datasets where exact interpolation should be avoided.

Derivative and Inequality Constraints

Incorporation of both derivatives and inequality constraints into RBF-interpolation can be achieved using generalized interpolation (Hillier et al. 2014) which employs a set of linearly independent functionals operating on RBFs. Linear functionals vary depending on constraint type. Derivative constraints such as gradients and directional derivatives

Radial Basis Functions, Fig. 1 Examples of RBF implicit modeling in geoscience: (a) overturned stratigraphic contact surface modeled using structural field observations: strike/dip orientations (red/blue colored tablets indicating stratigraphic top/bottom, respectively, of contact) and

green contact points from map traces and drill core; (b) ore grade modeling using metal assay data from drill core point samples (colored points). Iso-surfaces represent low, medium, and high ore grade

allow orientation data to be directly included into interpolation, overcoming challenges associated with the offset point approach for influencing modeled orientation. In addition, these constraints enhance continuity and extension of sampled structural features. Several scalar field interpolations using derivative constraints for orientation data (strike/dip with polarity) are shown in Fig. 2. Inequality constraints provide a means for imposing lower or upper bounds, as well as both, on data values. These constraints can also be leveraged for approximation purposes rather than exact interpolation (Fig. 2b). Furthermore, for structural modeling, inequality constraints can be used for rock unit observations where only their relative positions (e.g., above/below) to modeled surfaces are known. Determining optimal interpolants constrained by inequalities requires minimization of the interpolant's norm via quadratic optimization.

It is important to note that generalized RBF interpolants including geological interfaces, planar orientations, and tangent constraints (e.g., directional derivatives) are nearly identical to the interpolant from co-kriging in the dual form

(Lajaunie et al. 1997), differing only by the adoption of interface increments, indeed not surprising given the mathematical equivalence of RBF interpolation and kriging previously mentioned. Interface increments are constraints that permit the inclusion of multiple distinct surfaces simultaneously. To do so, a set of independent pairs of points for each distinct surface are constructed and added to the interpolant. The interpolation conditions for these constraints are the scalar field difference for each pair being equal to zero (e.g., points on the same iso-surface have equal scalar field values). Interface increments are particularly useful when modeling conformal stratigraphic geological volumes of rock and can also easily be implemented into the RBF interpolation using the same methodology.

Discontinuities

Discontinuous features can be incorporated into reconstructed scalar fields using RBF-based modeling. For 3D geological implicit modeling, discontinuous shifts in modeled rock volumes caused by geological faulting can be incorporated using

Radial Basis Functions, Fig. 2 Effect of different RBFs, methods, and parameters on scalar field interpolations for a synthetic dataset consisting of interface points (white circles) and strike/dip measurements with polarity (oriented line with arrow). Curve (black) represents the zero-valued iso-contour associated with the modeled interface. (a and b) cubic

radial power RBF that is fitted exactly and approximately (smoothed), respectively. (c and d) multiquadric RBF interpolations using different shape parameter ϵ values. (e and f) Wendland (C^2) RBF interpolations for two cutoff radii R

the three-step procedure developed by Calcagno et al. (2008). First, fault surface geometries represented by its own scalar field are modeled using corresponding fault constraints (e.g., fault locations, orientations). Second, descriptions for each fault's termination characteristics (e.g., infinite vs. finite) in addition to fault relationships (e.g., fault network), if applicable, using fault-fault relations are developed. The fault network relationships characterize the volumes of each fault's scalar field representation. Finally, to incorporate the sharp shifts in rock volumes across faults, discontinuous polynomial functions are added to the linear system Eq. 3 in a manner respecting the fault networks relationships.

Approximation Methods

Noisy and/or highly varying datasets can be problematic for exact RBF-interpolation. In these settings, geometrical artifacts and physically implausible solutions can be produced. Approximation methods are suggested for datasets possessing these attributes. There are four available approximation RBF-methods with varying degrees of implementation and computational complexity, including spline smoothing (Carr et al. 2001), use of inequality constraints, convolving an interpolant with a smoothing kernel (Carr et al. 2003), and greedy algorithms (Carr et al. 2001).

Spline smoothing simply requires user-specified values to be added to the diagonal elements of matrix A in Eq. 3. Larger values produce larger amounts of smoothing. However, choosing optimal values to add which are physically meaningful can be difficult. Obtaining the desired amount of smoothing requires a trial and error approach.

As previously mentioned, inequality constraints can be useful for approximation purposes (Fig. 2b). RBF-interpolants are optimal in the sense they have minimum norms where smaller interpolant norms correspond to smoother solutions. Since inequality constraints expand the range of possible solutions, interpolants that incorporate them will be smoother as compared to exact interpolation. The disadvantage of this approach is the additional computational complexity resulting from the quadratic optimization needed to obtain the minimum norm interpolants.

Convolution-based smoothing acts as a loss pass filter and is achieved by changing the interpolant's RBF with its associated smoothing kernel. A key advantage of this method is that the interpolant is only fitted once, and interpolant evaluations can use associated RBF-smoothing kernels with varying degrees of smoothing using the same fitted coefficients.

Greedy algorithms begin by fitting the interpolant using a small random subset of data. Next, residuals measuring the difference between data and interpolant values are computed on remaining points not included in the initial data subset by interpolant evaluation. Points corresponding to residuals beyond a user-defined threshold are added to the interpolant and refitted. The algorithm terminates when all residuals are

below the user-defined threshold. The disadvantage with this approach is the sensitivity to data outliers.

RBF Selection

RBF interpolation requires a specific RBF to be chosen for the interpolant (Eq. 1). Depending on data sampling, application, and model complexity (e.g., highly deformed geology), some RBFs may perform better than others. However, currently, there is a knowledge gap in determining the best RBF depending on these factors for geoscience applications and presents opportunities for future research. Nevertheless, awareness of the following two observations can be useful: (1) Interpolation differences between RBFs increase as data sparsity increases, (2) CPD RBFs listed in Table 2 generally perform well for surface modeling. The effect of using different RBFs (radial power, multiquadric, and Wendland) and associated parameters from Tables 1 and 2 on scalar field interpolations for a synthetic dataset is illustrated in Fig. 2. Interpolations presented in Fig. 2a, b using a cubic radial power RBF can be advantageous since they are parameter-free. For the multiquadric, smaller shape parameter values (Fig. 2c) ϵ correspond to flatter functions while larger values (Fig. 2d) correspond to smoother functions. For Wendland's compactly supported functions, the cutoff radii parameter R specifies the range of influence of sampled point data. Smaller R values are more locally based interpolations (Fig. 2e) whereas larger R values are more global (Fig. 2f).

The most common technique used for determining the optimal RBF and associated shape parameters (if applicable) given a dataset is leave one out cross-validation (LOOCV). This technique typically uses either error estimates or stability metrics of RBF interpolants. Although these metrics are useful to study mathematical properties of the interpolation, they are insufficient in determining which RBF and their parameters are best for producing physically plausible models for many geoscience applications.

Ideally, determining the best RBF for geoscience applications requires development of application-specific metrics computed on models produced by the evaluation of RBF interpolants over a discretized domain. The purpose of model metrics is to provide comparative measures for how much better one model compares to another. Model metrics can include various geometrical measures of smoothness and shape, topological measures computed from the Morse-Smale complex (Edelsbrunner et al. 2003), volume/area of regions bounded by function value ranges, and model uncertainty as measured by entropy from ensemble of models (de la Varga and Wellmann 2016). Combining model uncertainty with application-specific model metrics capable of measuring the performance and plausibility of relevant model features is recommended.

Software Implementations

There are numerous commercial and open source software-implementing RBF interpolation and associated methodologies. However, there are no implementations which offer comprehensive support for all possible optimizations and constraint types. Furthermore, some implementations obscure access and restrict fine tuning of various RBF parameters which can be beneficial for modeling. Access to specific RBF methods and control over their parameterization may require using open source code – albeit at the expense of ease of use. Additionally, there are potential synergies with combining RBF interpolation with other geomodeling tools which enable incorporation of additional geological information provided by interpretation, knowledge, and multi-disciplinary datasets.

Limitations

Although there has been great success with using RBF interpolation for spatially dependent geoscience applications, limitations exist, particularly with respect to geological modeling of structurally complex features. In these settings, physically implausible solutions can be produced. The predominant issue is limited control over global interpolation properties. A priori knowledge quite often available describing global properties such as topology, volume/area, and structural feature thickness cannot be incorporated as constraints, the reason being many global properties can only be computed after interpolants have been fitted. In addition, there are scalability problems. While RBF-based numerical optimizations enabled up to millions of data points using interpolants of the form Eq. 1, many of extensions previously described and their kriging counterparts have yet to be accommodated by these methods.

Recent Research

Potential for modeling capacity enhancement for geoscience applications using RBF interpolation may exist in leveraging recent research from the numerical analysis community. In particular, the variably scaled kernels introduced by Bozzini et al. (2015) transform the interpolation problem to a higher dimensional space permitting locally varying shape parameters for SPD RBF functions. The concept could provide a mechanism for incorporating locally varying anisotropy. For discontinuous applications, the work on variably scaled discontinuous kernels by De Marchi et al. (2020) would be of interest.

Conclusions

RBFs remain popular in geoscience for scattered data approximation for spatially dependent applications, particularly for implicit modeling. Although there has been widespread success in their use, there are limitations depending on the application. Notwithstanding the limitations, continued development of RBF-interpolation and their novel uses provides current and future geoscience applications with increasingly effective tools.

Definition

The random forest algorithm formalized by Breiman (2001) is a supervised learning method applied to predict the class for a classification problem or the mean value of a target variable of a regression problem. The fundamental elements of the algorithm consist of “classification and regression trees” (CART) that are applicable for modeling nonlinear relationships, particularly where the prerequisites of standard parametric regression, such as explicit functional expressions, independence of regressors, homoscedasticity, and normality of errors, cannot be met. Individual “trees,” sometimes referred to as decision trees, are built through the process of recursive partitioning of the predictor variable data space leading to a schematic of “nodes” and “branches” that depicts the relationships among the variables and their hierarchical importance. This iterative process splits the data into branches and then continues splitting each partition into smaller groups as the

partitions become more refined and the data more homogeneous within the partitions. The splitting rules may be set to maximize local-node homogeneity or optimize a criterion related to the predictive value of the target (dependent) variable.

The random forest algorithm constructs an ensemble of such decision trees using a training data set. This ensemble (“forest”) is instantiated with values of predictor variables to establish the class of the target variable (in the case of classification) or the value of the target variable (in the case of regression). The target variable represents the quantity to be determined and the predictors are variables whose known values are thought to be related to the target. The use of an ensemble approach, rather than a single tree, improves the predictive accuracy outside the training data set due to averaging the individual tree predictions and assures stability and robustness of the predictions because the ensemble encompasses more possibilities in the training data set (Hastie et al. 2009). In supervised learning, training data are the data used to train an algorithm to predict the target variable. If a separate validation data set is required, the training data may be a random subsample of the available data.

Description of Random Forest Algorithm

The random forest algorithm constructs an ensemble of trees in the following way. Each individual decision tree is developed from a bootstrap sample randomly selected with replacement from the training data set and subsequently built by recursively partitioning the predictor space. The recursive partitions are constructed by sampling a subset of the available predictors and then optimal splits in the predictor data space are identified that provide the greatest reductions in node impurity. The node impurity is a measure of the homogeneity of the target values at the node. For classification trees the standard algorithm minimizes Gini impurity, which is interpreted as the probability of misclassifying an observation. For regression trees, partitions are made to minimize the error variance of the target variables associated with the predictors. Bootstrap sampling of the training data to construct each tree, plus sampling the set of predictor variables prior to each partition, is intended to quantify uncertainty and reduce the prediction variance at the expense of introducing slight bias.

In the case of classification, the random forest ensemble prediction consists of the “majority vote” among all class assignments determined for the individual trees; and in the regression case, prediction consists of the mean of the predicted values of the target variable across all individual trees. For each tree, the part of the training data that is not included in the bootstrap sample used to construct the tree is known as the out-of-bag (OOB) sample. These data are used by the

algorithm to incorporate a validation step in the training procedure (Breiman 2001). The OOB error estimate is comparable to the error calculated with standard cross-validation procedures. The OOB error is an estimate of the random forest's "generalization error," which is defined as the prediction error expected for samples outside the training set.

Hyperparameters are used to control the learning process in the machine learning algorithms so that the predictive model minimizes the estimated generalization error. For random forests, they include the number of trees, the number of predictors sampled, the bootstrap sampling fraction of the training data, and various controls on tree complexity, such as the minimum number of observations to be used at a terminal node, the required observations for a partition (node size), and the maximum number of terminal nodes. A smaller subset of the predictors leads to lower correlation among trees. A smaller minimum node size leads to deeper trees with more splits. A smaller training sample fraction also leads to reduced correspondence among trees in the forest.

Model Interpretation

Model interpretation centers on the relative importance of the predictor variables and the responses of the target variable to incremental predictor variable changes. Two metrics for assessing the relative impact of predictors are permutation importance and Gini importance. Permutation importance ranks the predictor variables based on degradation of the model's predictive performance when their values in the OOB sample are randomly and successively permuted. Predictor variable importance rank is directly proportional to the degree of the loss in predictive accuracy for the OOB samples when predictor values are successively permuted. Alternatively, Gini importance counts the number of times a predictor is used in partitioning the predictor space weighted by the fraction of samples it splits (which approximates the probability of reaching that node) averaged over all trees of the ensemble. Gini importance rank corresponds to the relative magnitude of the calculated Gini importance. Because this traditional computational scheme for computing Gini importance produced biased results in favor of predictors with many possible split points, it was modified by Nembrini et al. (2018) and the revised version was shown to be unbiased. Other interpretive tools include permutation tests (Altmann et al. 2010) used to calculate p-values associated with the predictor variables. Innovative methods to compute prediction intervals (Zhang et al. 2019) and ways to generalize the algorithm to provide rigorous causal inference interpretations to the relationship between predictors and the target variable (Athey et al. 2019) are areas of recent research.

Because of their breadth, tree-based predictive models can capture the interaction effects of predictors. While identifying

and recognizing the nature of such interactions can be difficult, the use of various visual displays can be helpful. For example, the marginal effect that one predictor or two features have on the target variable can be shown by partial dependence plots (PDPs). By averaging predicted target values across trees, when marginal changes are made in one predictor, and other predictors are set at their average values, PDPs show whether the relationship between the target and a feature is linear, monotonic (i.e., entirely nonincreasing or non-decreasing), or more intricate. Another visual diagnostic is the individual conditional expectation plot (ICE). Whereas the PDPs show the predicted target values averaged across all trees, the ICE plot displays the individual tree values of the target relative to marginal changes in a predictor, thereby capturing the diversity of the predicted responses. Additional methods to identify, analyze, and interpret effects of predictor interactions are being pursued by researchers in a variety of other sciences, particularly medicine.

Analytical advantages include the nonparametric nature of the algorithm, its superior predictive performance, its capability to determine variable importance, built-in procedures to facilitate model validation using OOB observations, and the ability to compute variable proximities that can be used for data clustering to further improve prediction performance (Tyralis et al. 2019). Most implementations of the algorithm also provide imputation options to allow use of incomplete observations.

The analyst should be aware of the following limitations when applying the original random forest algorithm. First, the results are not as readily interpreted as those derived from a single regression or classification tree. Second, the reliability of the variable importance metrics is affected by correlation among predictors. Third, predictions cannot be reliably extrapolated beyond the range of the training data. Fourth, modifications are required to adequately model data sets in which the number of observations of the response variable belonging to one class is substantially different from the numbers of observations associated with the other classes (e.g., in the case of rare events such as some mineral occurrences). Finally, it is worth noting that the original algorithm is not suitable for causal inference. Further, variations of the random forest algorithm (e.g., extremely randomized forests or conditional inference random forests) do not consistently provide better performance (Tyralis et al. 2019).

Variations and Software

Tyralis et al. (2019) have published one of the most extensive reviews of the literature relating to random forests, all in the context of water and hydrogeological research. They list and reference 33 variations of the basic algorithm, with extremely randomized trees, quantile regression trees, and trees

associated with conditional inference being among those most frequently applied. Additional references for variations that lead to Bayesian, neural, dynamic, and causal random forests are also provided.

Computer software for modeling random forests is readily available in a number of open source domains and in many commercial packages. Tyrallis et al. (2019) list 55 packages related to random forests available in the R language, which is a free software environment for statistical computing and graphics. Python, also an open source language, has a random forest implementation in the Scikit-Learn package, and commercial software providers, such as Mathworks® and SAS®, commonly have packages for computing random forests (Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the US Government.).

Earth Science Applications

Numerous applications of the random forest algorithm and its variations have been published in the quantitative earth science literature. For example, applications of the algorithm to remote sensing are reviewed by Belgiu and Drăguț (2016). Another broad class of applications relate to predictive mapping at the regional level utilizing the classification function of the random forest algorithm. For example, mapping situations that use data generated from satellite images combined with various types of geophysical measurements (either from airborne sensors or field samples) can be used to classify rock lithology. In this case, the multiple classification scheme works on a pixel basis to generate the map image. Similar approaches have been applied to data on physiography, rainfall, and soil type to map areas having a propensity for landslides; and groundwater resources have been mapped using physiographic data, satellite imagery, and observed occurrences of springs (Tyrallis et al. 2019 and references therein). Other mapping applications include those involving land use and wetlands (Belgiu and Drăguț 2016).

During the last 50 years, geologists have developed an expert knowledge base identifying evidentiary data of individual classes of mineral occurrences. This information, along with spatial geologic data and occurrence/non-occurrence of minerals, can be addressed with the random forest algorithm to generate favorability maps for use in mineral prospecting (e.g., Carranza and Laborte 2016). Such applications, which include copper, gold, and polymetallic minerals, require adjustments to be made to the input data because the identified potentially marketable concentrations of mineral occurrences are quite rare.

Laboratory applications of the random forest algorithm include identification and location of organic matter and

pores in scanning electric microscope (SEM) images of organic rich shales. Similar image processing techniques can be used to analyze petrographic thin sections to predict (classify) rock type and mineral composition (Xie et al. 2020).

In the oil and gas industry, the random forest algorithm has been applied to well log images and digitally processed well logs to identify lithology and rock properties that become the basis for calculating oil and gas reservoir parameters. The algorithm is routinely used in field operations to classify rock lithology from well measurements taken while drilling in real time to identify the target formation as well as to predict rates of drilling penetration (Xie et al. 2020). Other uses include prediction of individual well flow rates and expected ultimate oil recovery by well. These latter applications of the regression tree function of random forests naturally lead to identifying the drivers of well productivity utilizing the variable importance function of random forests.

As well noted in Tyrallis et al. (2019), water science applications largely involve categorization of stream flow volumes and water quality features, as well as the analysis of predictor importance. Uses of the random forest algorithm to address environmental quality and ecological viability include mapping contaminants in estuarine systems, modeling nitrate concentrations in water wells, and prediction of algae blooms in tropical lakes. In these applications the algorithm is used to identify predictors that drive the models of such systems. In the atmospheric sciences, the use of random forests has been shown to improve severe weather forecasts when 2 and 3 days out from the event.

Summary

The random forest algorithm is broadly employed across multiple disciplines, with numerous variations having been developed for a wide variety of contexts and scenarios. Its use has become almost ubiquitous in the earth sciences, with applications ranging from research and planning to optimization of field and industrial operations, resource exploration and development, environmental monitoring, and beyond. Given the ready availability of software, execution of the basic algorithm is relatively straightforward, with computations and setup requiring minimal assumptions. Applications often encompass large data bases and thousands of predictors, and its superior predictive performance is well established in the earth sciences as well as in other fields such as the medical sciences. While not without limitations, the methodology underlying the algorithm is still an active field of research for generalization and statistical interpretation (Zhang et al. 2019; Athey et al. 2019).

Stochastic process

Definition

A random function $Z(\mathbf{x})$, also known as a stochastic process, can be defined as a rule that assigns a realization to the outcome of an experiment

$$Z(\mathbf{x}) \sim \{z(\mathbf{x}, \theta)\}, \forall \theta \in \Omega, \mathbf{x} \in \mathcal{D}, \quad (1)$$

where $\mathcal{D}$ is the domain within which the realization is defined (it could be finite or infinite, discrete or continuous); in geosciences, $\mathcal{D}$ will be the one-, two-, or three-dimensional portion of the space where the variable of interest is being studied, or, in many occasions, the point set of one-, two-, or three-dimensional locations centered at the voxels discretizing the study area; Ω is the sample space containing all outcomes of the experiments; $\mathbf{x}$ is a point in the domain $\mathcal{D}$; and θ an outcome of the experiment. For the reminder and without loss of generality, $\mathbf{x}$ will be regarded as a spatial coordinate.

Realization Versus Random Variable

A random function as defined above can be analyzed also in terms of random variables. When the experiment outcome is fixed at θ_0 , the function $z(\mathbf{x}, \theta_0)$ is a realization of the random function within the study area. But when the location is fixed at $\mathbf{x}_0$, the function $z(\mathbf{x}_0, \theta)$ corresponds to a random variable. To alleviate the notation, θ is dropped hereafter, and then, a lower case z will represent realizations (and the values they can take) and an upper case Z a random variable or the random function itself.

The random function can then be characterized by all the n -variate distributions

$$F(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n; z_1, z_2, \dots, z_n) = \text{Prob}(Z(\mathbf{x}_1) \leq z_1, Z(\mathbf{x}_2) \leq z_2, \dots, Z(\mathbf{x}_n) \leq z_n), \quad (2)$$

which are defined for any set of locations $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n\}$, and any set of values $\{z_1, z_2, \dots, z_n\}$.

To better understand what a random function is, it is convenient to consider this duality between realizations and random variables (Fig. 1). When considered as a collection of realizations, one needs to know which is the rule that associates a realization to the outcome of an experiment. When considered as a collection of random variables, one needs to know all its multivariate distributions.

The Random Function Model in Geosciences

Geoscience variables generally display patterns of spatial variability that cannot be modeled with deterministic models, and, at the same time, they display spatial patterns that denote that their distribution in space is not totally random. The random function model is a model suited for the modeling of these variables. A decision is taken that the specific, and unknown save for a few measurement locations, spatial distribution of the variable of interest corresponds with one of

Random Function, Fig. 1 Conceptualization of a random function as a collection of realizations, $Z(\mathbf{x}) \sim \{z_i, z_{ii}, \dots, z_0\}$. At any given location $\mathbf{x}$, the collection of z values through the realizations corresponds to a random variable

the realizations of a random function. Then, a random function is chosen and it is analyzed to build an understanding about the values of the variable at unsampled locations. The difficulty in adopting this model strives in how the random function is chosen, and then, how it is characterized, whether through the rule that associates realizations to experiment outcomes or through the multivariate distribution.

Some Random Function Summary Statistics

There are some summary statistics commonly used in the characterization of a random function. The first and second order ones are given next.

Expected Value

The expected value of a random function is a function of $\mathbf{x}$ with the expected values of each random variable

$$E\{Z(\mathbf{x})\} = \mu(\mathbf{x}). \quad (3)$$

Variance

Likewise, the variance of a random function is a function of $\mathbf{x}$ with the variance of each random variable

$$\text{Var}\{Z(\mathbf{x})\} = \sigma^2(\mathbf{x}) = E\{(Z(\mathbf{x}) - \mu(\mathbf{x}))^2\}. \quad (4)$$

Covariance

The covariance is computed between two locations and it corresponds to the covariance between the two random variables at those locations

$$C(\mathbf{x}_i, \mathbf{x}_j) = E\{(Z(\mathbf{x}_i) - \mu(\mathbf{x}_i))(Z(\mathbf{x}_j) - \mu(\mathbf{x}_j))\}, \forall \mathbf{x}_i, \mathbf{x}_j \in \mathcal{D}. \quad (5)$$

Variogram

Like the covariance, the variogram is also computed between two locations

$$\gamma(\mathbf{x}_i, \mathbf{x}_j) = \frac{1}{2} E\{(Z(\mathbf{x}_i) - Z(\mathbf{x}_j))^2\}, \forall \mathbf{x}_i, \mathbf{x}_j \in \mathcal{D}. \quad (6)$$

Stationary and Ergodicity

Refer back to Fig. 1, adopting a random function model implies the acceptance that one of the realizations $\{z_i, z_{ii}, \dots, z_0\}$ is the reality. Some data may have been sampled, but it is evident that, from these data, it is impossible to derive any of the common statistics described in the previous section, much less any of the n -variate distributions in Eq. (2). At $\mathbf{x}_1$, there is only one sample of the random variable $Z(\mathbf{x}_1)$, from which it is impossible to derive $\mu(\mathbf{x}_1)$, and the pair of values $z(\mathbf{x}_2)$ and $z(\mathbf{x}_3)$ are not sufficient to compute the covariance $C(\mathbf{x}_2, \mathbf{x}_3)$ or the variogram $\gamma(\mathbf{x}_2, \mathbf{x}_3)$. For these reasons, the random function models used in the geosciences are not as generic as their definition implies. It is typical to use random functions that are both stationary and ergodic.

Stationarity

A random function is said to be stationary of the first order if its expected value is constant

$$E\{Z(\mathbf{x})\} = \mu(\mathbf{x}) = \mu. \quad (7)$$

A random function is said to be stationary of the second order if its covariance depends only on the separation vector between the two locations and not in the actual locations. In Fig. 1, the pairs of points $z(\mathbf{x}_2)$ and $z(\mathbf{x}_3)$, and $z(\mathbf{x}_4)$ and $z(\mathbf{x}_5)$ are separated by the same vector; if the random function is stationary of the second order, the covariance would be the same for both pairs

$$C(\mathbf{x}_i, \mathbf{x}_j) = C(\mathbf{x}_i - \mathbf{x}_j). \quad (8)$$

When the separation vector is the null vector, the covariance becomes the variance of the random variable and, as a consequence of the previous equation, it will be constant

$$C(0) = \sigma^2. \quad (9)$$

Likewise, the variogram of a second-order stationary random function depends only on the separation vector

$$\gamma(\mathbf{x}_i, \mathbf{x}_j) = \gamma(\mathbf{x}_i - \mathbf{x}_j), \quad (10)$$

and the following two relationships hold

$$C(\mathbf{x}_i - \mathbf{x}_j) = \sigma^2 - \gamma(\mathbf{x}_i - \mathbf{x}_j) \quad (11)$$

$$\gamma(\mathbf{x}_i - \mathbf{x}_j) = \sigma^2 - C(\mathbf{x}_i - \mathbf{x}_j) \quad (12)$$

Ergodicity

A stationary random function defined on an infinite domain $\mathcal{D}$ is said to be ergodic on the mean when the constant expected value of all the random variables coincides with the mean computed on any realization

$$E\{Z(\mathbf{x}_j)\} = \int_{\mathcal{D}} z_{\theta}(\mathbf{x}) d\mathbf{x} = \mu, \quad \forall \mathbf{x}_j \in \mathcal{D}, \forall \theta \in \Omega. \quad (13)$$

Likewise, it is ergodic on the covariance when the expected value computed through the realizations can be replaced by the integral on any realization

$$\begin{aligned} C(\mathbf{x}_i - \mathbf{x}_j) &= C(\mathbf{h}) = E\{(Z(\mathbf{x}_i) - \mu)(Z(\mathbf{x}_i + \mathbf{h}) - \mu)\} \\ &= \int_{\mathcal{D}} (z_{\theta}(\mathbf{x}) - \mu)(z_{\theta}(\mathbf{x} + \mathbf{h}) - \mu) d\mathbf{x}, \\ &\quad \forall \mathbf{x}_i - \mathbf{x}_j \in \mathcal{D}, \forall \theta \in \Omega \end{aligned} \quad (14)$$

The Decision of Stationarity and Ergodicity

Given that, in practice, only limited information about one of the realizations of the random function is available, it seems convenient to use stationary and ergodic random function models since, in that case, the mean and covariance of the random function could be replaced by approximate estimates of the spatial integrals computed from the sample data. But the use of a stationary and ergodic covariance is only a matter of convenience, nothing that can be proved or disproved on the basis of sparse information from a given realization.

On certain occasions, the modeler may choose a non-stationary random function, for instance one with a space-varying expected value, but such a decision must be taken from ancillary data, like geological or process information but never on a statistical analysis of a single sample from multiple random variables.

Convenient Random Function Models

There are some random function models that are commonly used in mathematical geosciences for their convenience in specifying all n -variate distributions in Eq. (2).

The Multi-Gaussian Random Function Model

The multi-Gaussian random function model is probably the most commonly used because its multivariate distribution only depends on the mean and the covariance; all remaining higher-order moments are functions of these two (Anderson

1984). A stationary and ergodic multi-Gaussian random function has the advantage that mean and covariance can be estimated from the mean and covariance derived from the data using Eqs. (13) and (14).

The Multi- φ -Gaussian Random Function Model

The properties of the multi-Gaussian random function model extend to any monotonic transformation $Y(\mathbf{x}) = \varphi(Z(\mathbf{x}))$. The new random function $Y(\mathbf{x})$ is the collection of realizations $\{y_{\theta} = \varphi(z_{\theta})\}$ and has the same property of being fully characterized just by the mean and the covariance, as long as function φ is monotonic. A typical example is the multi-log-Gaussian distribution used frequently to model permeabilities.

The Indicator Random Function

One of the problems associated with the adoption of any Gaussian-related random function has to do with its convenience of being fully characterized by the mean and the covariance. The full dependency of all higher-order moments on the first two moments makes it impossible to control the higher-order moments, and, particularly, the multi-Gaussian models are characterized by little spatial connectivity for the extreme values (Gómez-Hernández and Wen 1998). Extreme-value continuity is fundamental in geological settings; in petroleum engineering, shale barriers or flow channels can depict much higher continuity in space than intermediate values, and such a feature cannot be reproduced by a Gaussian random function.

The continuity of extreme values is explicitly handled by the indicator formalism. Consider that the range of z values is binned into K classes and then K indicator variables are derived for any z value

$$i_k(\mathbf{x}; z) = \begin{cases} 1; & \text{if } z \in [z_{k1}, z_{k2}] \\ 0; & \text{if not} \end{cases}, k = 1, \dots, K \quad (15)$$

where $[z_{k1}, z_{k2}]$ are the limits of class k . As a result, now there are K random functions $I_k(\mathbf{x}; z)$ the continuity of which can be controlled independently of each other and can be used to build non-Gaussian realizations of $Z(\mathbf{x})$.

Algorithmically Defined Random Functions

According to Eq. (1), the set of realizations generated by current stochastic simulation computer codes define a random function, as long as an unequivocal rule identifying each realization is defined. Such a rule is the algorithm behind the computed code. The experiment consists of drawing random seed number to prime the algorithm. To each seed corresponds a unique realization.

In the beginning, computer simulation codes were built to generate realizations drawn from a specific random function model. This is the case for any sequential Gaussian simulation code (see, for instance, Deutsch and Journel 1992; Gómez-Hernández and Journel 1993; Gómez-Hernández and Srivastava 2021), which, by construction, will generate realizations drawn from a multi-Gaussian random function. Likewise, any sequential indicator simulation code (Gómez-Hernández and Srivastava 1990; Deutsch and Journel 1992) generates realizations from an indicator random function. But soon after these codes were of general use, practitioners demanded codes that generated realizations with other characteristics. For example, there was an interest in generating realizations from a stationary random function with univariate distributions far from a Gaussian bell and with a given covariance. This could not be achieved with any Gaussian simulator. To solve this problem, the direct sequential simulation was proposed (Soares 2001), this algorithm generates realizations with the desired univariate distribution and covariance; however, the other moments or n -variate distributions are unidentified, but they could be derived from the statistical analysis of a sufficiently large collection of realizations.

The concept of algorithmically defined random function was born and the need to have the analytical expression for the n -variate distributions of Eq. (2) disappears. The most recent multipoint geostatistics (Mariethoz and Caers 2014; Strebelle 2002) would be a paradigmatic example of these kinds of random functions defined by a collection of realizations, which are built on the basis of a training image and an algorithm to extract high-order statistics from the training image to infuse them onto the realizations.

Summary and Conclusions

The random function model is often used in the geosciences to model the spatial variability of properties that display a heterogeneity that cannot be described deterministically nor is completely random. From a practitioner point of view, the use of such a model is a decision that cannot be proved or disproved from the data. The random function model is the foundation of geostatistics and is behind standard algorithms such as kriging or sequential simulation.

Random Variable

Ricardo A. Olea
Geology, Energy and Minerals Science Center,
U.S. Geological Survey, Reston, VA, USA

Background

When Galileo dropped objects from the leaning tower of Pisa, he noted that, for a given height and meteorological condition, the falling time was the same. This is one example of a situation in which the result of the experiment is unique and predictable. These types of observations are called deterministic experiments.

Now flip a coin. The result is not unique anymore. More than one outcome is possible; the result is now uncertain. These experiments go by the name of random experiments.

Statistics uses the concept of probability to measure the chances of different outcomes in a random experiment. By convention, probabilities are always positive numbers including zero. There are three fundamental probability axioms (Hogg et al. 2018):

- The probability of an impossible outcome is 0.
- The maximum value of 1 denotes outcomes absolutely certain to occur.
- If two outcomes of the same experiment cannot occur simultaneously, their probabilities are additive.

Probabilities can also be multiplied by a factor of 100 and reported as percentages. A set containing all possible outcomes is called sample space.

Definition

A random variable is a function that assigns a value in a sample space to an element of an arbitrary set (James 1992; Pawlowsky-Glahn et al. 2015). It is a model for a random experiment: the arbitrary set is an abstraction of the experimental conditions, the values taken by the random variable are in the sample space, and the function itself models the assignment of outcomes, thus also describing its frequency of appearance. In simpler terms, for the purpose of this presentation, a random variable is a function that assigns to each of the outcomes of a random experiment a value with a certain probability. A random variable also goes by stochastic variable and aleatory variable. Random variables are usually annotated as Roman capital letters, such as X or Y .

The characteristics of the sample space may define a variety of random variables. When the sample space comprises the real numbers and the scale is assumed absolute, differences are computed by ordinary subtraction, and averages are computed using the ordinary sum. However, there is a need of alternative sample spaces. For instance, a set of functions of time; a set of bounded regions on a plane; the points on a simplex; points on a sphere; positive real numbers. They characterize the respective random variables as stochastic processes, random sets, random compositions, random

directions, and ratio scale variables. These types of random variables deserve separate development of their theories.

A random variate or realization is the result of randomly drawing one outcome from a random variable.

Discrete and Continuous Random Variables

In order to fully characterize a random variable, a description of the probability of the outcomes is necessary. The nature of the sample space determines the kind of description. In terms of the type of the sample space, the random variables can be discrete or continuous. If one can count the number of possible outcomes, then the random variable is discrete. Outcomes from game chances such as flipping coins, playing cards, or casting dice are examples of discrete random variable sample spaces. Fig. 1 shows two examples that provide chances in random experiments with only two possible outcomes per trial. The case when the chance of each outcome is the same can be associated with the cumulative number of heads expected after flipping a coin multiple times (Fig. 1a). When the value of the parameter is 0.1, it gives the expected number of producing wells when drilling wildcats in different plays (Fig. 1b). In the discrete case, a probability mass function assigns the probabilities to each outcome.

A continuous sample space has different mathematical characteristics. For this presentation, we center the attention in random variables whose sample space is identified with the real numbers. Commonly, the description of the probability in this continuous case is determined based on a probability

Random Variable, Fig. 1 Examples of discrete random variables when repeating a random experiment with only two possible outcomes 12 times: (a) number of heads or tails in flipping a fair coin; (b) number

of new reservoirs successfully discovered when drilling 12 wildcats at different plays when considering that the probability of success per well is 10%

density function, $f(x)$. If X is a univariate random variable, the probability of X to be in an interval (a, b) is given by

$$\Pr[a \leq X \leq b] = \int_a^b f(x) dx. \quad (1)$$

With this kind of definition, a single point is always assigned a null probability. It should be remarked that the probability density function does not always exist but when it does, it is always nonnegative. When the limits of integration in Eq. 1 are $(-\infty, \infty)$, the result is the area under the curve, which must be 1 to agree with the axioms in the Background section.

Analytical and Numerical Random Variables

The results in Fig. 1 can be obtained by actually running experiments or from mathematical analysis. In the latter case, the result is a probability mass function that in this case goes by the name of binomial distributions (Forbes et al. 2011). The binomial distribution is an example of a discrete analytical probabilistic model:

$$f_b(x) = \frac{n!}{x! \cdot (n-x)!} \cdot p^x \cdot (1-p)^{n-x}, \quad x = 0, 1, 2, \dots, n; \quad 0 < p < 1, \quad (2)$$

where n is a positive integer.

The normal or Gaussian distribution is one of the most widely used continuous analytical models because many attributes either follow or approximate a normal distribution (Papoulis 2002):

$$f_N(x) = \frac{1}{\sigma \cdot \sqrt{2\pi}} \cdot \exp \left[-\frac{1}{2} \cdot \left(\frac{x - \mu}{\sigma} \right)^2 \right], \quad 0 < \sigma, \quad (3)$$

where μ and σ are two parameters allowing the same expression to take different shapes, such as those in Fig. 2. The distribution is always symmetrical with respect to parameter μ , which coincides with the mean of the distribution. Parameter σ controls the spread of the distribution and coincides with the value of its standard deviation. The domain of the normal distribution is $(-\infty, \infty)$, which sometimes is a problem in the geosciences because no attribute takes infinite values, and some do not take negative values.

The advent of computers is increasingly popularizing the generation of random variables by general purpose methods such as the Monte Carlo method or the bootstrap method. Figure 3 is an example of a repeated realization of a random variable – a random sample for short – describing the volume

Random Variable, Fig. 2 Examples of normal distributions. Parameter μ determines the center of the distribution, and σ the spread and height of the peak

Random Variable, Fig. 3 Example of a numerical random variable showing all possible values of the true gas volume in a gas reservoir

of natural gas to be produced from a petroleum reservoir. In this case, the modeling was based on estimated ultimate recovery of natural gas from several wells (Olea et al. 2010). In this situation, the outcomes are all the possible values that the true volume could have. Note that the possible values are not equally likely. Relative to the coin example in Fig. 1a, the interpretation of the random variable is different now. By no means is the random variable implying that the gas volume in the one reservoir can take different values. In this case, there is just one unique true value, say, 125.2 billion cubic feet, but that value is unknown. The whole purpose of using a random variable is to learn what to expect about the magnitude of the true value.

Random Variable, Fig. 4 Example of numerical approximation of oil volume random variable: (a–e) input random variables, all following shifted and scaled beta distributions; (f) resulting oil volume using 5000 draws per attribute

Combination of Random Variables

Even in the simplest case of a real sample space, the arithmetic of random variables can be complex, so the analytical results are quite limited. The simplest cases for operation, for instance sum or product of real random variables, are those in which the random variables involved are independent. Two random variables are independent when their joint probability density function is the product of their individual probability density functions. This means that the result of one of the random variables does not influence the realizations of the other one. A well-known classical example is that of two independent normal random variables X and Y . In such a case, their sum follows another normal distribution with a mean equal to the sum of the means, and the variance is equal to the sum of the variance of X plus the variance of Y .

The advent of computers has radically increased the capabilities to work with combinations of random variables. Today, the Monte Carlo methods can be used to consider unlimited combinations of random variables. For example, suppose one were interested in a probabilistic assessment of the unknown volume of oil in place within the drainage area of an oil well. Let H be the random variable representing the net formation thickness, A the drainage area, P the porosity, W the water saturation, and B the conversion factor to standard conditions. The volume V of the oil in place is given by (Terry and Rogers 2014):

$$V = 0.0001 \cdot \frac{H \cdot A \cdot P \cdot (100 - W)}{B}. \quad (4)$$

This is an expression complex enough not able to be solved analytically regardless of the form of the five random variables. However, if the modeler can provide distributions for all five random variables, then it is possible to obtain a numerical distribution for the random variable V by repeatedly drawing random variates from those distributions by applying the Monte Carlo method. At least 1000 iterations are recommended for stable results. In the example, for the first set of draws the values were 16.353 m (H), 43,038 m² (A), 9.912% (P), 31.149% (W), and 1.2 (B). The oil volume for those values is 40.026 thousand m³ (V). The result of performing the draws and calculations for another 4999 times are presented in Fig. 4. Both α and β are shape parameters of the beta distribution whose domain can be shifted and linearly scaled to vary within any finite boundaries (a, b) (Olea 2011):

$$f_{\beta}(x) = \frac{x^{\alpha-1}(1-x)^{\beta-1}}{\int_0^1 u^{\alpha-1}(1-u)^{\beta-1} du}, \quad 0 < x < 1; \quad \alpha, \beta > 0. \quad (5)$$

Summary and Conclusions

A random variable is a convenient concept to link outcomes of random experiments to elements in another set. Random variables play a fundamental role in probabilistic modeling of uncertain attributes, from simple experiments like flipping coins, to more complex computer-aided calculations, such as determining the volume of crude oil resources in a reservoir.

Rank test

Definition

Rank score tests use the index of sorted observations to make inference, rather than the observations themselves. There are several rank tests in the literature. They are all based on the index which sorts the observations, rather than on the values. With this approach, rank tests gain robustness. We refer the reader to the book by Hollander et al. (2013) for a comprehensive account of nonparametric techniques. Girón et al. (2012) used such tests for edge detection in SAR imagery.

Consider the two-sample case in which we want to compare $\mathbf{x} = (x_1, x_2, \dots, x_m)$ and $\mathbf{y} = (y_1, y_2, \dots, y_n)$. Denote $\mathbf{xy} = (x_1, x_2, \dots, x_m, y_1, y_2, \dots, y_n)$ the joint sample. Unless explicitly stated, we will assume that all observations are different. Denote by $\mathbf{R}_x$ and $\mathbf{R}_y$ the vectors of sizes m and n which correspond to the ranks of $\mathbf{x}$ and $\mathbf{y}$ in the joint sample, respectively.

The literature is not unanimous in the names for the following tests. We will follow the denomination presented by Hollander et al. (2013).

Wilcoxon Rank Sum Test

This is a generic test for the hypothesis that x and y are the result of drawing observations from the same distribution, i.e., $\mathcal{H}_0: F_X(t) = F_Y(t)$ for every $t \in \mathbb{R}$. Typical alternatives are of the form $\mathcal{H}_1: F_Y(t) = F_X(t - \Delta)$. These alternatives are called “location-shift model,” and describe a “treatment effect” measured by $\Delta = E(Y) - E(X)$. With this, the null hypothesis reduces to $\mathcal{H}_0: \Delta = 0$.

The Wilcoxon test uses the sum of the ranks of the second sample $\sum_{i=1}^n \mathbf{R}_y(i)$. It is possible to compute its expected value and variance, with which we form the test statistic:

$$W = \frac{\sum_{i=1}^n \mathbf{R}_y(i) - n(m+n+1)/2}{\sqrt{mn(m+n+1)/12}}. \quad (1)$$

Under the null hypothesis, and when both $m, n \rightarrow \infty$, then W is asymptotically distributed as a standard Normal random variable. This asymptotic result leads to the following decision rules:

- Reject $\mathcal{H}_0$ in favor of $\mathcal{H}_1: \Delta > 0$ if $W \geq z_\alpha$;
- Reject $\mathcal{H}_0$ in favor of $\mathcal{H}_1: \Delta < 0$ if $W \leq -z_\alpha$;
- Reject $\mathcal{H}_0$ in favor of $\mathcal{H}_1: \Delta \neq 0$ if $|W| \geq z_{\alpha/2}$,

(in which z_α is the α quantile of the standard Normal distribution)

Mann-Whitney Test

A different approach for the same tests presented is based on the Mann-Whitney statistic:

$$U = \sum_{i=1}^m \sum_{j=1}^n \mathbb{1}_{x_i < y_j},$$

where $\mathbb{1}_C$ denotes the indicator function of condition C . The statistic U relates to Wilcoxon's W statistic by $W = U + n(n+1)/2$, and thus, they produce equivalent tests.

van der Waerden's Test

Consider the van der Waerden's test statistic given by

$$V = \sum_{j=1}^n \Phi^{-1} \left(\frac{R_y(j)}{m+n+1} \right),$$

where Φ^{-1} is the inverse of the cumulative distribution function of a standard Normal random variable. This test statistic has symmetric distribution under $\mathcal{H}_0$. Its critical values are available through, among others, the **waerden.test** function from **R**'s **agricolae** package. The van der Waerden's test is an attractive competitor of Wilcoxon's W test.

Summary

There are several tests that use ranks rather than observations for assessing the null hypothesis that two samples $\mathbf{x}$ and $\mathbf{y}$ were produced by the same distribution $\mathcal{H}_0: F_X(t) = F_Y(t)$. They have the advantage of less sensitivity to outliers than tests that use the values directly. The performance of nonparametric tests is comparable to their parametric versions when the samples are large.

Computer Science, Hyderabad, India

Fig. 1 C. R. Rao, courtesy of Dr. Tejaswini Rao, daughter of C. R. Rao

Biography

Statistical methods are widely employed in all areas of activities of society including industry and government. Professor Calyampudi Radhakrishna Rao has made distinct and extensive contributions to several branches of the subject of statistics and its applications leading to efficient methods of statistical analysis. These include the theory of estimation, multivariate analysis, characterization problems, combinatorics, and the matrix algebra. In the area of estimation, Rao established that, under specific conditions, the variance of an unbiased estimator of a parameter is not less than the reciprocal of the Fisher information contained in the sample. This result became known as the Cramer-Rao inequality. He has also shown that one can possibly improve an unbiased estimator by a process known as Rao-Blackwellization; Rao developed tests known as the Score and Lagrangian multiplier

tests based on large samples for testing simple and composite hypotheses under general conditions.

Based on the properties of suitable sample statistics, Rao obtained a number of characterizations of the normal, Poisson, Cauchy, stable, exponential, geometric, and other distributions. General classes of distributions known as weighted distributions were introduced in his work on discrete distributions arising out of the methods of ascertainment. The problem of defining a generalized inverse of a singular square or rectangular matrix was studied by Rao and he developed the calculus of generalized inverses of matrices with applications to unified theory of linear estimation of parameters in a general Gauss-Markov model.

In multivariate analysis, one has to deal with extraction of information from a large number of measurements made on each sample unit. Not all measurements carry independent information. It is possible that a subset of measurements may lead to procedures which are more efficient than using the whole set of measurements. Rao developed a test to ascertain whether or not the information contained in a subset is the same as that given in the complete set. He also developed a method for studying clustering and other interrelationships among individuals or populations. Using general diversity measures applicable to both qualitative and quantitative data, the method of analysis of diversity was developed by Rao for which he introduced the concept of quadratic entropy in the analysis of diversity.

Combinatorial arrangements known as orthogonal arrays were introduced by Rao for use in the design of experiments. These arrangements are widely used in multifactorial experiments to determine the optimum combinations of factors to solve industrial problems. These have also applications in coding theory. An important result of practical interest resulting from this novel approach is the Hamming-Rao bound associated with orthogonal arrays.

Calyampudi Radhakrishna Rao was born on September 10, 1920, in Huvvina Hadagall in the state of Karnataka in India. After finishing his high school and basic undergraduate education, he went to Andhra University in Visakhapatnam, a coastal city in the state Andhra Pradesh where he obtained his B.A.(Hons) at the age of 19. After deciding to pursue a research career in mathematics, Rao went to Calcutta where he joined the Indian Statistical Institute (ISI) for training in the subject of statistics. At the same time, he completed a master's degree program in statistics at Calcutta University. Later Rao obtained his Ph.D. degree at Cambridge University in the UK after which he became a full professor at ISI at the young age of 29. Upon retiring from the ISI in 1980, he moved to the USA where he worked for another 40 years and currently is a research professor at the University of Buffalo in New York State. He received several awards including the Bhatnagar award and the India Science award from the Government of India, the National Medal of Science from USA, and was

elected as fellow of several academies of Science in India and abroad. In total he received 39 honorary doctorates from universities in India and other countries. Several students received their Ph.D. degrees under his guidance. C. R. Rao is among the worldwide leaders in statistical science over the last several decades. He celebrated his 100th birthday on September 10, 2020.

Biography

Professor S. V. L. N. Rao was born on May 11, 1928, in India. He studied at Andhra University and obtained his B.Sc. (Hons) and M.Sc. degrees by 1950. He started his career in 1952, as an instructor in geology at the Indian Institute of Technology (IIT) Kharagpur. By 1975, he rose to the position of professor at the same institute. He obtained his Ph.D. degree in 1959. During 1985–1987, he served as Head of the Department of Geology and Geophysics. His role in the establishment of the Remote Sensing Service Centre at the IIT campus with the funding from the Department of Science and Technology (DST) was instrumental.

Rao, earlier worked on geochemistry problems, and as a postdoctoral fellow at Kingston, Canada, he learned the use of computers while he pursued crystallography studies.

From the late 1970s, his research interests have shifted to the applications of geostatistics and mathematical morphology in satellite and geological data analysis (Rao and Srivastava 1969; Rao and Prasad 1982). As a researcher and visiting professor, he visited several countries including Canada, Hungary, Germany, France, Norway, the UK, and the USA. He served as an adviser and consultant to provide solutions in mineral exploration and mine planning work for National Mineral Development Corporation and Hindustan Zinc Limited. On the invitation of the then Vice-Chancellor of Andhra University, he joined the Andhra University, where he headed the Center for Remote Sensing and Information Systems as a Director (1988–1992) and also served as Professor of Computer Science and Systems Engineering. He has guided about 40 Ph.D. students in geophysics, geology, remote sensing, mathematics, and computer science during his four decades of teaching and research. He played an instrumental role in starting an M.Tech course in remote sensing in 1988 as the Founding Director of the Center for Remote Sensing and Information Systems. From several conversations, it was obvious that he benefited from his collaboration with Late Professor Barth of Chicago University, Late Professor Berry, the then President of American Mineralogical Society, Prof. Jean Serra, Centre de Morphologie Mathematique, and Professor Jef Johnson of Open University. In 1984, he was invited to Paris School of Mines, where he worked with Jean Serra on optical microscopy, and he was involved in developing approaches for the quantitative treatment of polarized microscopy in geology. While he worked with Jef Johnson, Prof. Rao proposed the principle of dilational similarity.

His colleagues and students remember Professor Rao as a distinguished geochemist, geostatistician, and computer scientist, and as a selfless friendly thesis adviser. He was an associate editor for the *Mathematical Geology* that released a special issue in his memory (Sagar 2001).

Realizations

C. Özgen Karacan

U.S. Geological Survey, Geology, Energy and Minerals
Science Center, Reston, VA, USA

Definition

In statistics, a realization is an observed value of a random variable (Gubner 2006). In mathematical geology, the most important realizations are those in the form of maps of spatially correlated regionalized variables.

Spatial description of random variables within complex domains and making certain decisions about those require complete knowledge of the attribute of interest at each point in space. However, it is virtually impossible to sample from every location within the domain to gain a complete spatial understanding of the random variables with certainty at different scales. Therefore, limited sampling leaves us with incomplete information, which is the source of uncertainty. Understanding the uncertainty and quantifying it are essential to minimize the risks of decision making. Geostatistical simulation techniques aim to quantify spatial uncertainty of random variables by numerically reproducing the reality, which we have limited knowledge of, in a discretized (node) domain. The process creates multiple alternative maps of the random variable, which are called realizations. These are numerical representations of reality constructed by obeying the constraints of spatial statistics of the sampled data. Realizations are discretized maps explaining the uncertainty of the property of interest.

Methods of Generating Realizations

Realizations can be generated through interpolation methods (e.g., kriging), or simulation methods that rely on two-point statistics (e.g., sequential Gaussian simulation, sequential indicator simulation), or multiple point statistics (e.g., FILTERSIM and SNESIM), which utilize a training image (TI) (Remy et al. 2009). The choice of the most appropriate method may depend on the objectives and the theoretical and practical aspects of the work. For instance, interpolation methods tend to be practical, but they generate only one realization where spatial variations are smoothed along with a kriging variance surface. The drawback is that quantifying joint uncertainty of the model at unsampled locations is not possible. Also, the local variations are suppressed through smoothing, which may not be a realistic representation of reality.

Simulation methods (either relying on a variogram or a TI) are more commonly used to generate realizations since these

methods can generate multiple realizations through a stochastic process. Depending on the needs, data limitations, spatial complexity, and the objectives of the work, either a variogram-based method or a multiple point simulation algorithm along with a TI as a conceptual model to define local patterns can be used to generate realizations. The realizations generated through multiple point simulations generally exhibit local patterns similar to those conceptualized in the TI (Pyrcz and Deutsch 2014).

Simulations may or may not be conditioned to the data in sampling locations, depending on the approach. Conditional simulations honor the data at sampling locations while estimated values vary outside the sampled locations constrained by spatial continuity, trend, and secondary information (Pyrcz and Deutsch 2014). On the other hand, in realizations generated using the unconditional approach, locations of high- and low-estimated values do not necessarily correspond to the actual locations of the high- and low- sampled data as they are not preserved at their locations. Therefore, conditional simulation is preferred more often to generate realizations.

The Concept of “Equiprobable”

Multiple realizations generated by repeating the entire simulation process are used to assess the joint uncertainty of the model at unsampled locations. Each realization obeys the input statistics and trends, as well as the data at sampling locations. Since each of these realizations are generated by repeating the same stochastic process during simulations and are constrained with the same data and spatial correlations, they are equally likely to occur and equally likely to be the representation of reality. Therefore, they are often called “equiprobable.” However, equal probability refers and applies to generation and representativeness of realizations when they are considered individually. In reality, when all realizations that represent the same attribute are evaluated with a criterion that is important for the goals of the project, some realizations are more similar to others and that class has a higher probability within the entire population of realizations. Therefore, the term equiprobable is true for individual realizations in the sense that each of them is one of the outcomes of the simulation process with equal probability. However, they may not have the same probability when they are ranked.

Number of Required Realizations, Screening, and Ranking

With the vast number of realizations that can be generated through stochastic simulations, it is important to determine the optimum number of realizations needed as well as the

minimum screening and ranking criteria. Simulation algorithms can generate tens or hundreds of realizations depending on the need. However, as the number of nodes and the number of realizations increase, computational time and data storage requirements increase and may become physical limitations. For the purposes of generating a realization population for ranking and for practical purposes of spatial uncertainty assessments, usually 100 realizations can be considered optimal. This number of realizations forms a robust population for visualization, uncertainty assessment, and ranking for use in other models.

There are a set of criteria discussed by Leuangthong et al. (2004) for screening and acceptance of realizations. If these criteria are not met within acceptable range, realizations cannot be considered as representations of reality as they are intended to. According to these authors, realizations should reproduce (1) *data values at their location* – a crossplot of the data and the simulated values at the data locations should be generated to see if the data follows the 1:1 line; (2) *the histogram of the attribute of interest and basic statistics* – A “Q-Q” plot of realization data versus the data at sampling locations can be utilized to compare the two distributions, which should follow the 1:1 line. Alternatively, global reproduction of the histogram can be examined on a few randomly selected realizations. The key features to note are the histogram shape, the range of the simulated values, and the summary statistics, such as the mean, median, and the variance; (3) *the spatial continuity of the data* – the variogram should be calculated for multiple realizations and compared to the input variogram model in the same directions. The model variogram should be reproduced within acceptable ergodic fluctuations.

Ordering and ranking of the realizations, for both visualization and use in other models, can be achieved by capturing

the similarities and differences between them. De Barros and Deutsch (2017) argue that calculating the Euclidean distance between the realizations can be an effective approach, as well as other distance measures including the use of connectivity and other flow-related properties, or weighting the realizations according to calculated resources, such as gas quantity. For example, Fig. 1 shows a ranking of 100 total gas in place (GIP) realizations of a coal-bearing strata and the realization corresponding to P_{50} of the probability distribution.

Further Evaluation of Realizations for Mechanistic Model Uncertainty

Generation of realizations is rarely the only and the final objective of geostatistical simulations, unless realizations are for resource assessments (e.g., gold quantity or coal tonnage). For example, in petroleum engineering studies, the final product can be an uncertainty model defining reservoir architecture to aid in making optimum decisions for given injection/production scenarios. Therefore, once realizations are compiled and pass the minimum screening and acceptance criteria, they may be ranked or subjected to post-processing for use in mechanistic models, such as reservoir simulations (e.g., realizations of porosity, permeability, or gas in place) for conducting sensitivity analysis of reservoir response.

When utilizing realizations in flow models, for example, either all realizations, or ranked realizations with defined marginal probabilities (P_5 , P_{50} , and P_{95}), or the E-type models or local percentile models can be used (Karacan and Olea 2015; Thanh et al. 2020). An E-type model, which is the local average of all realizations at each node, provides an indication of the most likely value of each reservoir property at a specific node. Similarly, local percentile models can be calculated

Realizations, Fig. 1 Histogram of total gas in place (GIP) realizations generated using sequential Gaussian simulation for ranking, and the P_{50} realization

from the realizations and are good indicators of areas with definitive high or low values (Fig. 2). The advantage of sequentially using all realizations of properties, on the other hand, is the ability to fully assess uncertainty and to investigate the sensitivity of reservoir response to all equiprobable representations of reality. If this is not possible, or practical,

E-type models or ranked realizations can also be used to define model architecture and assess uncertainty of reservoir behavior.

Historical oil or gas production data can be extremely useful for further assessing realizations to refine the architecture of the reservoir and to assess its uncertainty through

Realizations, Fig. 2 Local probabilities calculated for GIP value > 1.133 (mean) using 100 realizations for the same coal-bearing strata from Fig. 1

Realizations, Fig. 3 Comparison of predicted gas production rates of a coalbed methane well with the measured rates using 100 realizations generated for different properties (white lines). The results with realization number 69, the E-type model, and the average of the best

realizations (BR) are marked. Permeability realizations (in md) corresponding to those production profiles are shown on the right-hand side. (Modified from Karacan and Olea 2015)

history matching. If production data are available, the simulation results generated either using all or ranked realizations, such as E-type or different percentiles, can be compared to well-production data. For instance, if a certain combination of realizations does not produce similar production values, then these realizations can be removed from the set as possible options, thereby reducing model uncertainty (Pyrz and Deutsch 2014). Figure 3 shows a comparison of predicted coalbed methane gas production with the measured production when all 100 realizations of different properties are used in the model. Three predictions are shown on Fig. 3 (1) Predictions provided by the E-type model; (2) the realization that gives the minimum error for all wells (realization number 69); (3) the average of the realizations that minimize the error for each of the wells (best realizations). The permeability realizations corresponding to those three gas production profiles are also shown. E-type models generate reasonable production results. However, using all realizations allows for fully assessing uncertainty and for selecting individual models that best describe the reservoir architecture and contained resources (Karacan and Olea 2015). Therefore, although each realization is an equiprobable representation of reality at the geostatistical simulation level, the realizations are not equiprobable when it comes to defining the architecture of mechanistic models, as shown by the reservoir response (Fig. 3).

Summary and Conclusions

Geostatistical simulation methods generate a model of uncertainty with multiple sets of spatially distributed possible values. One set of possible outcomes is referred to as a realization. Realizations can be generated using variogram-based or TI-based methods using either conditional or unconditional approaches. Since simulations use a stochastic approach, they can generate a range of tens to hundreds of realizations, depending on the objective and physical limitations of the modeled system. However, regardless of the number of realizations, they must pass certain screening and acceptance criteria constrained by the data at sampled locations to be considered as a representation of reality and deemed useful for further post-processing or analysis. Realizations can be ranked using different distance criteria. Ranked or post-processed realizations can then be used for many different purposes spanning from resource assessments to building mechanistic models for assessing uncertainties.

Definition

Ordinary least squares (OLS) regression assumes that the independent variable on the X-axis is measured without uncertainty or error, and the dependent variable on the Y-axis is measured with error. However, reduced major axis (RMA) regression assumes errors in both the dependent as well as in the independent variables and minimizes the sum of the diagonal (vertical and horizontal) distances of the data points from the fitted line (Harper 2016). In geosciences, the measurements are usually exposed to several types of error that vary in magnitude and sources. For example, remotely sensed aerosol optical depth (AOD) measured with either ground instruments (such as Sunphotometers) or satellite-based sensors have errors with different magnitudes, although errors are higher in satellite-based than ground-based sensors. However, irrespective of the magnitude of the error in the independent variable X-axis (ground-based measurements) and dependent variable Y-axis (satellite-based measurements), the errors in both variables

should be considered in regression analysis. For modeling the relationship between dependent and independent variables both having an error, RMA regression is preferable to OLS regression, which assumes that the X-axis variable is measured without error (Sokal and Rohlf 1981). Moreover, if the error rate in the independent variable surpasses one-third of the error rate in the dependent variable (which is common in geosciences), then RMA regression should be considered (McArdle 1988). Firstly, RMA normalizes the variables and then fits a line of slope (β), which is the geometric mean of lines degenerating X on Y and Y on X (Sokal and Rohlf 1981). The RMA slope can be positive and negative, depending on the correlation (r) sign. However, the RMA slope is unaffected by the decreasing value of r .

Introduction

Data representation, whether geophysical observations, numerical models, or laboratory results, using the best fit line is a conventional method in the scientific and other fields. In this regard, the most common statistical methods such as ordinary least squares (OLS) regression and reduced major axis (RMA) regression are used to demonstrate a relationship between two variables (dependent and independent). However, in geosciences, both the dependent and independent variables are assumed to have errors. Specifically, remote sensing data provided by both satellite-based and ground-based instruments, have errors due to instrument calibration, algorithm uncertainties, and changing environmental conditions, etc. Therefore, to define the best fit line between remote sensing data used in geosciences applications, RMA is recommended rather than OLS (Bilal et al. 2019, 2021). The utility of RMA is demonstrated in a case study, where both RMA and OLS regression were applied to aerosol remote sensing data obtained from the MODIS (Moderate Resolution Imaging Spectroradiometer) operational Level 2 aerosol products and ground-based AERONET (Aerosol Robotic Network) Sunphotometer Version 3 Level 2.0 measurements. The remotely sensed MODIS aerosol data have pre-calculated expected errors depending on the inversion method, and similarly, the AERONET measurements have some uncertainties. The AERONET measurements are considered as standard (independent variables) for the validation of satellite-based aerosol remote sensing data (dependent variable). Therefore, the use of RMA is more suitable and recommended, as both the dependent variable (satellite remote sensing data) and independent variable (AERONET Sunphotometer measurements) have errors.

Methods

Ordinary Least Squares (OLS) Regression

Ordinary Least Squares (OLS) regression analysis is based on the assumption that the X (independent) variable is measured without an error or uncertainty and the Y (independent) variable is having an error or uncertainty. However, both X and Y variables (data) may have errors, especially, remote sensing data in the geosciences. Generally, in OLS regression, the errors in the dependent variable are ignored, but these errors should be considered for remote sensing data in the geosciences (Curran and Hay 1986). The OLS regression equation can be expressed as Eq. (1):

$$Y = (\alpha_{(OLS)} + \beta_{(OLS)}X + \varepsilon) \quad (1)$$

where

$\beta_{(OLS)}$ is the slope of OLS, $\alpha_{(OLS)}$ is the intercept of OLS, and ε is the error. The $\beta_{(OLS)}$ and $\alpha_{(OLS)}$ are calculated using Eqs. (2) and (3), respectively (Harper 2016):

$$\beta_{(OLS)} = \frac{S_{XY}}{S_{XX}} \quad (2)$$

$$\alpha_{(OLS)} = \bar{Y} - (\beta_{(OLS)})\bar{X} \quad (3)$$

where

$\bar{X}$ is the mean of the X variable, $\bar{Y}$ is the mean of the Y variable. The S_{XY} and S_{XX} can be calculated using Eqs. (4) and (5), respectively:

$$S_{XY} = \sum_{i=1}^n (X_i - \bar{X})(Y_i - \bar{Y}) \quad (4)$$

$$S_{XX} = \sum_{i=1}^n (X_i - \bar{X})^2 \quad (5)$$

Reduced Major Axis (RMA) Regression

Reduced major axis (RMA) regression is based on the assumption that both the X (independent) and Y (independent) variables are measured with error or uncertainty. RMA has many potential applications in numerous disciplines including remote sensing applications in geosciences. For validation of remote sensing observations against reference (in situ) data, where both observations and reference data have errors, RMA is a better choice compared to OLS (Curran and Hay 1986). Several studies in the fields of remote sensing applications in geosciences (Drury et al. 2008;

Li et al. 2019; Lin et al. 2014) have used RMA regression to define the best fit line between dependent and independent variables. The slope ($\beta_{(RMA)}$) and intercept ($\alpha_{(RMA)}$) of the best fit line of the RMA regression method are calculated using Eqs. (6) and (7), respectively (Harper 2016):

$$\beta_{(RMA)} = \left(\frac{S_{XY}}{S_{XX}} \right) / |r| \quad (6)$$

$$\alpha_{(RMA)} = \bar{Y} - \left(\beta_{(RMA)} \right) \bar{X} \quad (7)$$

where

$|r|$ is the absolute value of the Pearson correlation coefficient (r), and the slope ($\beta_{(RMA)}$) calculated using Eq. (6) can be positive or negative. The slope ($\beta_{(RMA)}$) can also be calculated using Eq. (8) and the positive or negative sign of the slope depends on the sign of the Pearson correlation coefficient (r).

$$\beta_{(RMA)} = \pm \frac{\sigma_Y}{\sigma_X} \quad (8)$$

where

σ_Y is the standard deviation of the Y (dependent) variable and σ_X is the standard deviation of the X (independent) variable.

Evaluation Method

To report the performance and errors in the RMA and OLS regression models, the mean bias error (MBE; Eq. 9), the root-mean-squared difference (RMSD; Eq. 10), and the mean systematic error (MSE; Eq. 11) are used. The MSE is considered as a significant method to show the difference between the trend-line of the independent (X) and dependent (Y) data, where a small value of MSE indicates a good trend and a large value of MSE denotes a trend has an error.

$$MBE = \frac{1}{n} \sum_{i=1}^n (\hat{Y}_i - X_i) \quad (9)$$

$$RMSD = \sqrt{\frac{1}{n} \sum_{i=1}^n (\hat{Y}_i - X_i)^2} \quad (10)$$

$$MSE = \frac{1}{n} \sum_{i=1}^n (\hat{Y}_i - X_i)^2 \quad (11)$$

Where $\hat{Y}$ is the predicted value obtained from the RMA and OLS regression models.

Results and Discussion

This study used remotely sensed aerosol optical depth (AOD) data from both satellite and ground-based Sunphotometer to demonstrate the performance of both the RMA and OLS models. Figure 1a shows the scatterplot and linear fit between MODIS AOD retrievals against AERONET Sunphotometer AOD measurements (reference data) calculated with both RMA (red line) and OLS (orange line) methods. The results show a better slope ~ 1.01 for RMA compared to the ~ 0.77 slope for OLS, which indicates a significant underestimation by 23%. However, no significant over- and underestimations were observed in the slope calculated by RMA. The results also showed a smaller MSE of 0.004 and RMSD of 0.063 for the RMA model compared to the OLS model (MSE = 0.006 and RMSD = 0.079). However, both the regression models showed the same MBE of -0.063 . To further demonstrate the performance of RMA vs. OLS, satellite-based rainfall retrievals were validated against ground-based rainfall measurements (Fig. 1b). A significant difference was also observed in slope and intercept calculated by RMA compared to those calculated by OLS with small errors (RMSD, and MSE). These results suggest the better performance of RMA regression, especially in terms of slope calculation, compared to OLS, and recommend the use of the RMA regression model for geoscience research applications.

Summary and Conclusions

In geosciences, satellite remote sensing data are usually required to validate against ground-based instrumental measurements. However, both datasets depend on instrumental calibration, which may introduce errors in the datasets. Therefore, the use of appropriate regression analysis is required to model the relationship between dependent and independent variables, which can consider errors in both variables. However, in general, the OLS regression method is most commonly used in geosciences to model the relationship between two variables, and it is assumed that the independent variable is measured without error, although this rarely occurs. On the other hand, the RAM method models the relationship between two variables considering errors in both the dependent as well as independent variables. Therefore, RMA regression should be considered more suitable for satellite remote sensing applications. To demonstrate the performance of RMA against OLS, remotely sensed satellite-based aerosol and rainfall data were validated against ground-based measurements. The results showed that the RMA regression is better able to model the relationship between the variables

Reduced Major Axis

Regression, Fig. 1 Reduced major axis (RMA) regression vs. ordinary least squares (OLS) regression. (a) Validation of MODIS AOD retrievals against AERONET AOD measurements and (b) Validation of satellite-based rainfall retrievals against ground-based rainfall measurements. Where the dashed black line represents the 1:1 line, the red line represents the line of the reduced major axis (RMA) regression, and the orange line represents the line of the ordinary least squares (OLS) regression

compared to OLS regression in terms of slope, small MBE, RMSD, and MSE. This study recommends that selecting a proper regression method is essential for modeling relationships in geoscience data and that RMA regression is more suitable than OLS.

Acknowledgments The authors would like to acknowledge NASA's Level-1 and Atmosphere Archive and Distribution System (LAADS) Distributed Active Archive Center (DAAC) (<https://ladsweb.modaps.eosdis.nasa.gov/>) for MODIS data and Principal Investigators of AERONET sites for AOD measurements. Definition

Regression analysis is a statistical approach to find the mathematical relationship between input independent variables and output dependent variables using linear/nonlinear equations. The regression model (also called as linear or nonlinear equation) is used to predict the values of output variable for the given values of input variables.

Introduction

The Earth's resources like vegetation, minerals, water, etc. are monitored using remote sensing. Remote sensing data analysis is based on statistical methods like regression, classification, and clustering (Richards and Jia 2006). Regression (also identified as prediction) involves obtaining output values of themes such as temperature, slope, pressure, elevation, etc., for the respective input values (Jensen 2004). One of the major applications of regression analysis is the prediction of weather parameters like pressure, temperature, and humidity using the data obtained from the sensors. Data classification is labeling the pixels in images to the classes like land use/land cover, weather parameters, etc. Clustering is an unsupervised data analysis approach in which the data points (also called as pixels in the image) are grouped into clusters without class labels (Theodoridis and Koutroumbas 1999). The clustered data points are assigned with corresponding class labels using ancillary data and ground truth.

The information related to Earth resources is represented in the form of digital images (Matus-Hernández et al. 2018). A digital image is mathematically defined as 2D function. The digital image consists of finite elements called pixels (Lillesand and Kiefer 1994). The digital images in remote sensing vary from monochromatic to multispectral and hyperspectral images (Campbell 1987). In multispectral and hyperspectral images, the pixels are also defined as pixel vectors or patterns (Bishop et al. 1995). A pattern is an entity associated and characterized by features (Duda et al. 2000). The pixel vector is a point in N-dimensional feature space. Regression analysis is predicting the output values for the unknown patterns based on the existing output values of patterns in the dataset (Doan and Kalita 2015). Regression analysis is implemented using a mathematical model by fitting a linear/nonlinear equation from the training data (Matus-Hernández et al. 2018).

There exist various methods of regression analysis for remote sensing application. These methods are broadly classified as linear and nonlinear approaches. The detailed description of these methods is given in following sections. Different methods of regression analysis are discussed in section “[Type of Regression Analysis in Remote Sensing](#).” The evaluation methods of regression analysis are given in section “[Evaluation of Regression model](#).” The results of linear regression model for an example dataset is provided in section “[Example: Linear Regression](#).” The relevant conclusion of regression analysis is given in section “[Conclusions](#).”

Type of Regression Analysis in Remote Sensing

The functional block diagram of the regression model is provided in Fig. 1. The input pixels/patterns are used to prepare the required dataset to fit the regression model. The data is preprocessed, and later, the dataset is divided into training set, testing set, and validation set. The training set is used to fit the equation for the regression model. The regression models are classified as linear or nonlinear models based on the relationship between input variables and output variable. A linear equation representing linear regression model is used to predict the values of the output variable if there exists a linear relationship between input variables and output variable. The equation for a single input variable linear regression model is given as:

$$y = a_0 + a_1x \quad (1)$$

where y is the output variable, x is a single input variable, and a_0 and a_1 are coefficients. Similarly, a nonlinear equation is used to fit a regression model if the relationship between input feature and output feature is nonlinear. In non-linear

Regression, Fig. 1 Regression model for remote sensing data analysis. The model considers input data, preprocessing of input data, fitting the linear or nonlinear equation, classifying/clustering the data, assigning the class label, and obtaining the classified map

regression analysis, a polynomial equation is used to fit the relationship between the dependent variable (output variable) and independent variable (input variable). The n th order polynomial equation for the nonlinear single input regression model is given as:

$$y = a_0 + a_1x + a_2x^2 + \cdots + a_nx^n, \quad (2)$$

where a_0 , a_1 , a_2 , and a_n are coefficients.

The regression models are also classified based on the dependence of the output variable on the number of input variables (features). The models are classified as single output-single input regression model, single output-multi-input regression model, multi input-multi-output regression model. The single output single input regression model predicts the values of the output variable which is dependent on the single input variable. The mathematical equation for single output-single input regression model is given in Eq. 1. The single output-multi-input regression model is used to predict the values of output variable which depends on multiple inputs. The equation for single output multi-input regression model is given as:

$$y = a_0 + a_1x_1 + a_2x_2 + \cdots + a_nx_n, \quad (3)$$

where a_0 , a_1 , a_2 , $\dots$, a_n are coefficients and x_1 , x_2 , and x_n are input variables or features. The models such as neural networks are used for multi-input-multi-output regression analysis.

The regression model is tested with the test dataset by passing each pattern/pixel vector and predicting the values of the output variable. The regression model is validated using the validation dataset. The predicted values of the patterns/pixels are then classified by using various supervised/unsupervised classification techniques. The major supervised classification techniques include K-NN, minimum distance to mean, neural networks, decision trees, and random forest. The unsupervised classification techniques include clustering techniques like K-means clustering, hierarchical clustering,

density-based SCAN, etc. The patterns are labeled with the corresponding class labels to obtain the output classified map.

Evaluation of Regression Model

The performance of the regression model is evaluated using three important performance metrics like R square, root mean square error (RMS), and mean absolute error (MAE). R square is the square of the correlation coefficient (R), and it is the measure of variability in dependent/output variable. Root mean square error is the square root of mean square error. Mean square error is the sum of the square of predicted output value and the actual value divided by the total number of samples. RMS error is calculated as:

$$RMS = \frac{\sum_{i=1}^n (y_i - y_i')^2}{N} \quad (4)$$

where N is the total number of patterns/pixels and n is the n th pixel in N number of pixels. y_i is the actual value of output variable, and y_i' is the predicted value of output variable.

The mean absolute error (MAE) is the sum of absolute value of error divided by total number of pixels.

$$MAE = \frac{\sum_{i=1}^n |y_i - y_i'|}{N} \quad (5)$$

The values of evaluation metrics for the regression model lies between 0 and 1 while 0 indicates less error and 1 indicates the maximum error.

Example: Linear Regression

In the present study, two datasets were considered to demonstrate model fitting for linear regression and polynomial regression. The first dataset consists of pixel values and

Regression, Fig. 2 Linear regression model to predict elevation values for the given pixel values (training set). The pixel values and the corresponding elevation values are collected from the SRTM digital elevation model (DEM) image

Regression, Fig. 3 Linear regression model to predict elevation values for the given pixel values (test set). The pixel values and corresponding elevation values are collected from the SRTM digital elevation model (DEM) image

corresponding ground elevation (*m*). The dataset is prepared by considering the SRTM DEM image with a spatial resolution of 90 m. The dataset is divided into the training set and test set. The training set is used to fit the linear regression model, and the test set is used to test the performance of the model. The linear regression model for the training dataset is given in Fig. 2. The linear regression model is tested on the test dataset, and the relationship between the predicted values and the input pixel values is given in Fig. 3.

The second dataset consists of pixel values and corresponding slope values. The dataset is generated from the raster slope map using QGIS. The polynomial regression model for the second dataset is given in Fig. 4. In Fig. 4, the *x*-axis represents the digital number (DN) or pixel value, and the *y*-axis represents the slope value. The fourth-order polynomial is used to fit the polynomial regression model for the second dataset. The performance of regression models was evaluated using three metrics such as RMSE, MAE, and *R* square. The values of three metrics were obtained between 0 and 1 for two datasets.

Conclusions

In the present study, the basic regression models for data prediction were presented with example datasets. Emphasis is given on regression models such as linear, polynomial, single input-single output, and single output-multi-input. In the present study, two datasets were considered as an example to demonstrate the functioning of linear and polynomial regression analysis for both training and test cases. The model was evaluated using the metrics like *R* square, MSE, and MAE, and the values were obtained between 0 and

Regression, Fig. 4 Polynomial regression model to predict slope values for the given pixel values. The pixel values and corresponding pixel values are collected from a raster slope map generated using QGIS

1. Furthermore, there exist advanced regression models like logistic regression, robust regression, probit regression, ridge regression, etc., to predict the values of the output variable.

Definition

Remote sensing (RS) is the science of making inference from measurements made at distance without any physical contact with the objects under study. It refers to identification of earth features by detecting electromagnetic (EM) radiation that is reflected and/or emitted by the surface at various wavelengths. It is based on the scientific rationale that every object reflects/scatters a portion of electromagnetic energy incident on it. The reflection depends on physical and chemical properties of the material. The object also emits radiation depending upon its temperature and emissivity.

Introduction

Visual perception of objects by the human eye is an example of remote sensing. However, it is confined to visible portion of EM spectrum. Modern remote sensors are capable of detection of electromagnetic radiation extending from gamma rays, x rays, and ultraviolet to infrared and microwave regions. While, in general, the medium of interaction for RS is through the electromagnetic radiation, gravity and acoustics are also employed in some specific circumstances. However, acoustic RS is very limited because it requires a physical medium for transmission. Aerial remote sensing started way

back in 1858 from balloon-based photography of Paris and later through rocket-propelled camera systems by the Germans in 1891. The first image of the Earth from space was taken by the Explorer 6 satellite of the United States in August 1959. Systematic Earth observation started with the launch of Television Infrared Observation Satellite (TIROS-1) on April 1, 1960, designed primarily for meteorological observations. Remote Sensing as we understand today gained momentum after the launch of Earth Resources Technology Satellite-1 (ERTS, later renamed as LANDSAT 1) in 1972 by the National Aeronautics and Space Administration, USA. The basic objective of earth remote sensing is to obtain inventory of natural resources in a spatial format at different time intervals, to ascertain their condition, to observe dynamics of the atmosphere and oceans, and to help understand various physical processes in an integrated manner. Subsequent to the launch of LANDSAT-1, many space agencies of different countries and some private players have successfully launched a number of RS satellites.

Physical Basis and Signatures

Study of the interaction of EM radiation with matter at different wavelength regions is paramount to remote sensing. Electromagnetic radiation covers a large spectrum from the very short wavelength gamma rays ($<10^{-10}$ m) to long radio waves (10^6 m). Mostly visible (0.4–0.7 μm), the reflected infrared (IR) (0.7–3 μm), the thermal IR (3–5 μm and 8–14 μm), and the microwave region (0.3–300 cm) are used in RS. The sun acts as a source of EM radiation used in passive optical remote sensing. As per Planck's law, all bodies at absolute temperatures above zero degrees Kelvin emit EM radiation which is a function of wavelengths (λ) and temperature.

$$E(\lambda, T) = \frac{2hc^2}{\lambda^5} \frac{1}{e^{hc/\lambda kT} - 1} \quad (1)$$

where $E(\lambda, T)$ is spectral radiant emittance in ergs/s, $h = 6.625 \times 10^{-27}$ erg sec (Planck's constant), $k = 1.38 \times 10^{-16}$ erg/K (Boltzmann constant), $c = 3 \times 10^{10}$ cm/s (Speed of light), and T is absolute temperature in °K.

The earth may be considered as a blackbody at ~ 300 °K emitting EM radiation with peak emission at around 9.7 μm . While EM radiation at shorter wavelengths (visible and near IR) interacts with a few micrometers of the earth surface, EM radiation at microwave wavelengths has greater subsurface penetration capability. Different land cover features, like water, soil, vegetation, rocks, cloud, and snow, reflect visible and infrared light in different ways. Vegetation reflectance is mostly governed by photosynthetic pigments in visible region

(400–700 nm), in near-infrared region (0.75–1.35 μm) by the leaf structure, and in the shortwave infrared by the presence of water. As vegetation becomes stressed or senescent, chlorophyll absorption decreases (blue and red regions). The reflectance ratio of the near infrared to red is known as a sensitive indicator of vegetation growth/vigor. Typical soil spectral signature shows lower reflectance in lower wavelength and high reflectance at larger wavelength. Water is relatively an absorber in the near-infrared and middle-infrared wavelength. This property helps in delineation and inventory of even small wetlands. Phyto-planktons present in inland wetlands, the coastal water, and ocean are associated with absorption due to chlorophyll pigment in narrow spectral regions facilitating their estimation. Snow exhibits high reflectance up to 0.8 μm and relatively low reflectance in middle infrared. Clouds look uniformly bright throughout the range 0.3 to 3 μm due to, nonselective scattering. Emissivity signature in thermal infrared region provides information on mineral composition. Most of the rock-forming silicate minerals have their diagnostic features in 8–14 μm . Remote sensing in the microwave region (frequencies between 10^9 and 10^{12} Hz) is highly useful as it provides observation of the earth's surface regardless of day/night and the atmospheric conditions. It also provides certain unique properties of targets in view of its ability to penetrate and its interaction with electrical properties of the targets. Microwave response is dependent upon its frequency, incidence angle, and polarization and also on emissivity characteristics of targets. The radar equation relates received signal with radar parameters and the target characteristics. For monostatic radars, it is given as

$$P_r = \frac{\lambda^2}{(4\pi)^3} \int \frac{P_t G^2 \sigma^0}{R^4} dA \quad (2)$$

where P_r = average power returned to the radar antenna from an extended target, P_t = power transmitted by the radar, G = gain of the antenna, R = distance from the antenna to the target, λ = wavelength of the radar, and σ^0 = the radar-scattering coefficient of the target.

Spectral response measured at the ground level is modified by the intervening atmosphere when measured by spaceborne sensor. Therefore, it is essential to understand and quantify the atmospheric effects on the radiation transfer between Sun, Earth, and sensor. Spectral regions where the EM radiation is transmitted through the atmosphere with little attenuation are called atmospheric windows. Manifestation of interaction of EM radiation with nonpoint targets is characterized by signatures comprising wavelength-wise spectral variations; changes in the reflectance or emittance, spatial variations; changes in the reflectance/emittance determined by the target characteristics' (shape, size, and texture) temporal variations; diurnal and/or seasonal changes in reflectance or emittance

and polarization variations; and variations in the polarization of EM wave reflected or emitted. Signatures are statistical in nature and not deterministic.

Sensors, Platforms, and Orbits

One needs a variety of instruments/sensors with a great degree of sensitivity and viewing geometries to study the interaction of EM radiation with the earth surface, atmosphere, and oceans. Sensors are broadly categorized in two categories, i.e., passive or active sensors. Passive sensors detect natural radiations either emitted or reflected from the earth. Active sensors have their own source of radiation to illuminate the target materials and detect the scattered EM wave. Initially the photographic cameras were widely used as imaging system. Currently, they are used in unmanned aerial vehicles (UAV) for various field surveys. Later, opto-mechanical scanners became a popular method of RS after photographic and TV cameras. Linear imaging self-scanning systems using charge-coupled devices are currently used to provide very high-resolution imagery and to avoid possible failures of the mechanical scan mechanisms. Sensor is characterized by spatial, spectral, and radiometric resolution. Spatial resolution refers to the ability of the sensor to distinguish and resolve the smallest object on the ground. Spectral resolution represents the spectral bandwidth (Full Width at Half Maxima) of imaging system. Radiometric resolution of sensor is quantified in terms of its ability to distinguish between smallest changes in the reflectance/emittance between various targets, generally quantified as noise-equivalent change in reflectance ($\text{NE}\Delta\rho$). Dynamic range is another important sensor characteristic, which refers to the measurements associated with minimum to maximum reflectance.

Hyperspectral instruments combine the concept of optical imaging (camera-/multi-spectral sensor) with well-established tools such as diffraction grating/Michelson/Sagnac interferometer, tunable filters for splitting light into narrow spectral components in airborne/spaceborne missions. Hyperspectral signature can detect the individual absorption features, since all materials are bound by chemical bonds; thus, they can be identified by their spectral characteristics more accurately as compared to broadband multispectral imagers.

Passive Microwave radiometers are used to measure the energy emitted by the objects in the microwave region. Antenna receives the emitted energy, and the signal is processed to derive brightness temperature of the surface. The brightness temperature is a product of the absolute physical temperature and emissivity. Generally, microwave radiometers have coarse spatial resolution. Side-Looking Airborne Radar (SLAR) is a type of active imaging sensor, which measures backscattered microwave radiation. Small real

aperture antenna limits the spatial resolution of SLAR. Synthetic Aperture Radar (SAR) is a coherent side-looking radar system, which utilizes the flight path of the platform to simulate an extreme large antenna or aperture electronically and generates high-resolution remote-sensing image. SAR interferometry is a technique based on combining two SAR images of similar region imaged from different positions and/or times. It is used for the generation of digital elevation model/topographic mapping and detection of small coherent movements (differential interferometry). In case of optical sensors, heights are determined using along track or across track stereo viewing. Lidar is also used to determine surface heights. While a microwave altimeter uses a microwave pulse in nadir direction to estimate surface heights of sea, scatterometer detects the backscattered signal from the sea surface to quantify surface roughness of sea and in turn surface wind velocity. Microwave sounders are radiometers operating at suitably placed wavelengths of an absorption band of oxygen, water vapor, etc. to estimate vertical profiles of some physical parameters.

Platforms and Orbits: The sensors are mounted on suitable platforms. Platforms can be a tripod, balloon, aircraft, drone, and a spacecraft. The height of the platform dictates the spatial resolution and swath of image. In general, higher platform allows wide area coverage with lower spatial resolution. Spacecrafts are mostly three-axes stabilized to facilitate nadir viewing, though there were some spin-stabilized systems in the initial years. A spacecraft comprises various subsystems such as mainframe, payloads, attitude and orbit control, power, thermal, telemetry, tracking and control, propulsion, etc. In order to provide greater revisit/repeat observations, many identical satellites are flown in tandem. Geostationary and Near-Earth orbit are two main types of orbits used in remote sensing. In a geostationary orbit, the satellites are located at 36,000 km in the equatorial plane of the earth. Satellite appears stationary to the earth as a period of revolution of satellite and rotation of the earth matches in this orbit. Geostationary orbit has the advantage of high revisit period (15–20 min) but is limited by spatial resolution (few km.). Near-polar, sun-synchronous orbit located at few hundreds of km height is preferred for high-resolution imaging with constant solar illumination condition. Such orbits are used to take images of few meter resolution and ensure repetitive observations (few days) of a scene at same local time for various terrestrial applications. In addition, inclined orbits to the equator that are not sun synchronous are also employed in certain specific cases to obtain greater visits per day.

Data Preprocessing, Products, and Analysis

RS data acquired from the sensors onboard the satellites by the earth station is in digital form. The acquired data has to be

preprocessed and corrected for various factors such as (i) image features of the sensor; (ii) stability and orbit parameters of the platform; (iii) scene surface characteristics; (iv) motion of the earth including its curvature; and (v) atmospheric effects. Normally standard data products are generated applying geometric and radiometric corrections. The procedures employed for geometric correction generally treat distortions in two groups, i.e., those which are systematic (or predictable), and those which are essentially random. The former includes the effect due to the earth rotation, the earth curvature, deviation from nominal altitude and attitude, variations of the above deviations during the imaging of a scene, etc. Nonlinear behavior of detector, responsivity variation between the detectors, pixel dropouts etc. result in radiometric distortions. Data thus obtained is subjected to image processing/classification techniques to extract information on earth surface features. Inversion of spectral radiance measured by the sensor at the top of the atmosphere is used to derive various geophysical parameters using radiative transfer modeling, which in turn are used to understand physical processes related to biosphere, atmosphere, hydrosphere, cryosphere, etc. RS data are growing in scope, volume, and variety. Processing of such data involves development in field of data science and associated techniques, i.e., neural network, genetic algorithm, machine learning, artificial intelligence, and cloud computing. Calibration is important for generating precise RS data product and associated geophysical parameters. Correction factors for sensor-related radiometric errors are normally generated by extensive calibration measurements during laboratory tests as well as postlaunch campaigns over natural or artificial targets. Standard lamps, solar diffuser reflectance panel, and blackbody are used for onboard calibration. Similarly, ground-based corner reflectors and spectrometric measurements are used for postlaunch calibration. Large patches of uniform and pseudoinvariant features like forest, desert, are also used for vicarious calibration. Data products/geophysical/biophysical parameters derived from system outputs are validated through field campaigns.

Remote-Sensing Applications

RS data are widely used in (i) inventory, monitoring, and condition assessment of natural resources viz. agriculture, forestry, minerals, water, and marine ecosystem, snow and glaciers, desertification, etc.; (ii) generation of thematic maps and updating of topographic maps; (iii) studying the atmosphere, cloud movements, and meteorology; (iv) locating living and nonliving ocean resources and in ocean state forecasting; and (v) disaster monitoring, mitigation, and early warning and in providing inputs to climate change studies. A variety of application programs, viz. agricultural crop production forecasts at national/regional level, forest

extents, identifying areas of deforestation, inventory of surface water bodies, snow cover, glaciers and their retreat, coastal zones, urban areas and their sprawl, exploration of geological resources, desertification, updating of topographic and thematic maps etc., help in planning resource management in many countries. Satellites-based observation of ocean and atmospheric is used to improve ocean-state forecasting and weather forecasting, and reduce exploitation of some of the ocean resources, in particular marine fisheries. Satellite observations have found an important and crucial role in facilitating early warning of some of the disasters, in monitoring and mitigation exercises, and in damage assessment. RS data have also been used in studying earth system science and in understanding various earth processes.

Summary and Future Direction

While earth observation from space has made significant contributions in studying different facets of the planet earth and its environment, there is a need to study the earth as a unified system of land, oceans, and atmosphere with its interlinkages and biogeochemical processes. Development of smaller and agile satellites in form of constellation and flying in formation are needed to achieve multidisciplinary/multitemporal observation capability. Technology has also helped in the collection of large volume of data, transmission, processing, and dissemination/distribution efficiently across the globe. With technological advances in Earth observation (resolutions, bands, coverage, sophistication of measurements, etc.), the concept of user segment has also seen a dramatic change. Although space technology has tremendously advanced the observation domain for many applications, there are still some challenges. Regional scale soil moisture, ocean salinity, surface pressure, vertical profile of winds, and vegetation florescence are some of the challenges, which need attention.

Reproducible Workflow

Anirudh Prabhu and Peter Fox

Tetherless World Constellation, Rensselaer Polytechnic Institute, Troy, NY, USA

Synonyms

Computational workflow; Reproducibility; Research workflows

Definition

Science advances on a foundation of trusted discoveries, reproducing an experiment is one important approach that scientists use to gain confidence in their conclusions. (McNutt 2014)

Reproducibility has been consistently identified as an important component of scientific research. Although there is a consensus on the importance of reproducibility along with the other commonly used “R” terminology (i.e., replicability, repeatability, etc.), there is some disagreement on the usage of these terms, including conflicting definitions used by different parts of the research community. In this article, we explore the different definitions used in scientific literature (specifically pertaining to computational research), whether there is a need for a single standardized definition and provide an alternative based on nonfunctional requirements. We also describe the role of reproducibility (and other R’s) in scientific workflows.

Reproducibility Versus Replicability: Various and Potentially Conflicting Definitions

Reproducibility has been extensively discussed in recent literature and been consistently mentioned as an important component of scientific research (Bechhofer et al. 2013; Stodden 2015; Plesser 2018; Goble 2016; Jasny et al. 2011; Miceli 2019; Peng 2009; Peng 2011). The first appearance of the phrase “reproducible research” in a scholarly publication appears in an invited paper presented at the 1992 meeting of the Society of Exploration Geophysics (Claerbout and Karrenbach 1992; Barba 2018). While there is widespread

agreement on the importance of reproducibility along with the commonly used “R” terminology, e.g., replicability and repeatability. There is some disagreement in the usage of these terms and their semantics: often their definitions are contradictory.

Broadly reproducibility and replicability have been defined along four different perspectives (Barba 2018; National Academies of Sciences, Engineering, and Medicine 2019):

1. There is no distinction between the terms and hence they can be used interchangeably (Bechhofer et al. 2013; Open Science Collaboration 2012; Stodden 2015). A few papers that do not distinguish between reproducibility and replication define various levels of reproducibility. These levels are defined based on either the specific domain of research or the scientific approach (Stodden 2011, 2013; Goodman et al. 2016).
2. Reproducibility refers to instances in which the similar results are obtained by a different team using a different experimental setup. For computational research, this focuses on an independent group obtaining similar outcomes using artifacts they develop independently (Plesser 2018; Goble 2016; Jasny et al. 2011; Association for Computing Machinery Version 1.0 2016; Drummond 2009).
3. Reproducibility refers to the ability of an independent team of researchers to obtain consistent results (the same results) with the same experiment as the original study/experiment. For computational research, this implies using the same data resources, algorithms, source code, and programming environment as the original study (Claerbout and Karrenbach 1992; Miceli 2019; Peng 2009; Association for Computing Machinery Version 1.1 2020; Walters 2013).
4. A reproducibility spectrum starts with a minimum standard for judging scientific claims and ends with full replication of the same results using the same data resources, algorithms, source code, and programming environment (Peng 2011).

Papers using approaches 2 and 3 have contradictory interpretations of the terms reproducibility and replicability. What approach 2 refers to as reproducibility is referred to as replicability in approach 3, and vice versa.

Is One Definition Needed?

With at least the four conflicting definitions, those cited in the previous section and many uncited in other review papers, the commonly asked question is: “it is possible to define reproducibility across domains and applications?”. Varying

answers are provided to this question, ranging from either picking a side in the conflicting definitions to just presenting an overview of the situation regarding terminology and its history (Barba 2018; Baker 2016; Plesser 2018). There does however exist some commonality between all of the definitions and interpretations of reproducibility, replicability, repeatability, and the other “Rs.” The commonality observed in all the interpretations are **how** reproducibility and replicability (or however it is referred to across scientific literature) are achieved. Thus, instead of choosing one of the existing definitions, or creating a new one, focus would be on **how** to design and execute “a more complete” scientific experiment/study. While the Association for Computing Machinery’s definitions (Association for Computing Machinery Version 1.0 2016; Version 1.1 2020) have taken one side and then the other in terms of defining reproducibility over the years, they also provide one aspect of introspection into the final task at hand. ACM appropriately divides the tasks for reproducibility or replicability (hereafter simply referred to as the “Rs”) as follows:

1. Same Team, Same Experimental Setup (STSE)
2. Different Team, Same Experimental Setup (DTSE)
3. Different Team, Different Experimental Setup (DTDE)

If we focus on the nonfunctional requirements, the **how** of these “Rs” rather the **what** they are called, then a more general consensus in science at times even across domains is possible. That is because at the highest level, the “Rs” will always fall into one of the three categories mentioned above. How researchers obtain consistent results for each of these three categorical conditions then becomes a way to distinctly define the “Rs” for each approach, be it statistical, computational, empirical, or experimental. For example, in STSE data-driven experiments (statistical and computational), one step includes setting a seed to reproduce results in methods that include randomization, especially statistical sampling or generating layouts of visualizations, etc. And in DTSE setups, a common step is to store all intermediate results along with detailed documentation of any and all data processing that takes place in the experiments.

Workflows

Dramatic increases in the volume of data collected in the geosciences in the last few decades have meant that there has been a trend involving the exploration of new data-driven research methods. In the field of informatics, scientific explorations usually follow a set of steps to get from accessing the raw data, processing it, visualizing, analyzing, and deriving insights to answer scientific questions. Such a sequence of steps is called a workflow.

Workflow Systems and the “Rs”

Workflow systems (or workflow management systems) have become increasingly popular as a way of specifying and executing data-intensive analysis (Davidson et al. 2008). A workflow system is a problem-solving environment, tuned to a distributed and service-oriented computational infrastructure (Ludäscher et al. 2006). Unlike general-purpose scripting languages, workflow systems automatically record the means by which results are produced (Davidson et al. 2008).

During the initial development of the scientific workflow systems, the “Rs” were not explicitly included or highlighted as part of the desiderata for workflow systems (Ludäscher et al. 2006; McPhillips et al. 2009; Oinn et al. 2004; Hull et al. 2006). With the avalanche of data caused by the development of new experimental technologies, scientists increased their focus on data-driven and computational research methods (Cohen-Boulakia et al. 2017). This change in focus resulted in a renewed interest in the reproducibility (or replicability) of these experiments. Cohen-Boulakia et al. (2017) examined popular scientific workflow systems in the context of the “Rs.” The authors do this by defining the various “Rs” (what they call levels of reproducibility) and introducing a set of criteria that play a major role in the ability of a workflow systems to be “reproducibility-friendly” for a given computational or data-driven experiment. Popular workflow systems such as Taverna, Galaxy, OpenAlea, VisTrails, and Nextflow were then examined in the context of reproducibility and their respective limitations were documented.

More recent platforms that help capture scientific workflows including the creation, execution, and publication of computational and data-driven experiments, such as Whole Tale (Chard et al. 2020), consider and promote the “Rs” as a central component of workflow design and execution.

“Rs” in Scientific Workflows

In reviewing extant literature and practice but without explicit statements confirming, we assert “While workflow systems have become popular recently, there is still significant portion of the scientific community that do not use workflow systems.” In order to make sure data-driven experiments achieve any one of more of the “Rs,” decisions need to be made during the workflow design process. This is especially important in case the workflows need to be reproduced (or replicated, etc.) by researchers in different research domains (which is fairly common in interdisciplinary scientific explorations). Design decisions must be made based on the nonfunctional requirements of the scientific experiments, i.e., based on **how** to design a reproducible (or replicable) workflow.

The categories mentioned in Peng’s reproducibility spectrum (Peng 2011) are as follows (starting with* the least reproducible to the gold standard):

1. Publication + Code
2. Publication + Code + Data

3. Publication + Linked and executable code + Data
4. Full replication (i.e., gold standard)

Since, in informatics, achieving the “Rs” involve releasing data and code, we focus the next section on how to design workflows and share the required data and code to get closer to the gold standard.

As put forward by Sandve et al. (2013), “rules” for considerations in workflow design for ensuring the “Rs” are fulfilled in the experiments are:

1. Keep track of how every result was produced
2. Avoid manual data manipulation
3. Archive the exact versions of external programs used
4. Version control all custom scripts
5. Intermediate results need to be recorded, preferably in formats standardized throughout the experiment
6. Note seeds set for analyses that include randomness
7. Store raw data behind plots
8. Generate detailed analysis outputs, allowing for inspections for summarization plots
9. Connect text statements to underlying results
10. Provide public access to scripts, runs, and results

Each of the above ten rules capture a specific aspect of the “Rs” and present what is needed in terms of handling the information and tracking procedures in order to release data and code for a scientific experiment (Sandve et al. 2013).

Releasing Data

Data used in an experiment/study can be obtained in a number of ways. It can range anywhere from being generated by the research team conducting the experiment/study, to being directly retrieved from an existing repository without making any changes to the data parameters. Usually, the process lies somewhere in the middle, where people need to retrieve the specific data required for their experiments from a few data repositories and make small additions or modifications to the data. In all of these cases though, there are some good practices to be followed so that the experiments achieve the criteria for the “Rs.” These steps are as follows:

1. Credit the creators of the data resource(s) being used. This may include citing a data paper, a dataset PID, or any citation/accreditation method stated by the dataset creators.
2. As the data is being processed, save versions of the dataset that are created during the execution of the workflow.
3. Document the code used for processing the data.

The datasets used in the experiment/study should be included along with the publication in many ways, such as:

- Releasing to data repositories like Zenodo, Dryad, Dataverse, Figshare, etc. (Assante et al. 2016).
- Adding data files as part of the supplementary materials for the main publication. Some journals host data associated with their publications.
- Publishing data papers in scientific journals or the more nascent, but specific, data journals (Callaghan et al. 2012).

Releasing Code

Releasing code is not only a central aspect of achieving the “Rs” for an experiment/study, but also helps highlight the algorithms used, and decisions made throughout the research workflow. Similar to releasing data, code has been released in many ways:

- Adding the code/script files used in experiment along with the papers in the supplementary materials.
- Releasing code files and scripts as a single research product to repositories like Zenodo, Figshare, etc. (Note: Unlike Dryad and Dataverse, Zenodo and Figshare are repositories that accept any research product, including code, presentations, videos, images, and softwares).
- Saving executable code for an experiment in an interactive environment like Jupyter or R notebooks, which are designed to support the workflow of scientific computing (Kluyver et al. 2016). Such notebooks can then be published to a repository for download and use or be linked to a working JupyterHub server. Services like mybinder.org enable sharing of projects containing live notebooks including a computational environment where user can execute code (Jupyter et al. 2018; Kluyver et al. 2016).

Writing code or scripts for an experiment/study are one of the steps where the research workflow is clearly visible. Hence, it is important to provide documentation with detailed instructions on how the individual code files tie into the larger research workflow. And also, correctly archive all the outputs (according to the rules put forward by Sandve et al. (2013)) required to achieve the “Rs.”

Summary

In conclusion, even though there are some disagreements on defining reproducibility or replicability, we observe some consensus on *how* to achieve reproducibility or replicability (the “Rs”). Also, there has been progress in the area of *data* and *code* releasing in the recent years which not only contributes to the “Rs” of scientific research, but also provides researchers who work in these areas much needed credit and an incentive to share their work outside of a scientific journal paper.

Rescaled Range Analysis

Gabor Korvin

Earth Sciences Department, King Fahd University of Petroleum and Minerals, Dhahran, Kingdom of Saudi Arabia

Definition

Rescaled-range analysis (R/S analysis) is a statistical method to detect and quantify long-term correlations in records of natural processes. It is a method to estimate the *Hurst exponent* H , which describes how the *rescaled range* of a *random process* X grows with time. If $X = \{\xi_t\}$ is a random process with mean value $\langle \xi \rangle$, its *range* R is the difference between the maximum and minimum of the cumulative X values:

$$R(l) = \max_{1 \leq t \leq l} X(t, l) - \min_{1 \leq t \leq l} X(t, l)$$

where l is length of the period considered and t is discretized time. Let $S(l) = \left\{ \frac{1}{l} \sum_{t=1}^l [\xi_t - \langle \xi \rangle]^2 \right\}^{1/2}$ be the standard deviation, then for many real-world processes the ratio R/S, called *rescaled range*, grows with time l as $R(l)/S(l) \propto l^H$. The exponent H is between 0 and 1, it is called “*Hurst exponent*” (to honor the British hydrologist H. E. Hurst, 1880–1978). When $0.5 < H < 1$, the behavior is *persistent* (the observed trend continues in the future), $0 < H < 0.5$ implies an *antipersistent* behavior, for $H = 0.5$ there is no long-range dependence between past and the future.

Rescaled Range and Its Scaling

Rescaled Range Analysis, the phenomenon later called *Hurst effect*, and the celebrated *Hurst exponent* H were discovered by the British hydrologist H. E. Hurst who worked in Egypt on designing an ideal reservoir. He used the following model (Hurst 1951; Korvin 1992: 328–329): Let X_t ; $t = 1, 2, \dots, N$ denote the net inflow of water into the reservoir in $N \gg 1$ consecutive years, $\bar{X}_N = \frac{1}{N} \sum_{t=1}^N X_t$ the average influx over the period, and suppose that every year we release this average period $\bar{X}_N$. In a given year t , $1 \leq t \leq N$, the reservoir will contain $X(t, N) = \sum_{i=1}^t (X_i - \bar{X}_N) = \sum_{i=1}^t X_i - t\bar{X}_N$ volume of water. If the reservoir is designed for N years, it must have a sufficiently large storage capacity $C(N)$ to assure that it never

overflows or gets dry, that is $C(N)$ must be larger than the difference $R(N)$ between the maximum and minimum amounts of water ever contained in the reservoir: $C(N) > R(N)$

$$R(N) = \max_{1 \leq t \leq N} X(t, N) - \min_{1 \leq t \leq N} X(t, N) \quad (\text{Eq. 1}).$$

$R(N)$ is called the *range* of the random variables X_i ; $t = 1, 2, \dots, N$, it depends on N and on the standard deviation $S(N) =$

$$\left\{ \frac{1}{N} \sum_{t=1}^N [X_t - \bar{X}_N]^2 \right\}^{1/2}. \text{ To eliminate this dependence, Hurst}$$

(1951) introduced the *rescaled range* $R^*(N) = \frac{R(N)}{S(N)}$ (Eq. 2). To understand how $R^*(N)$ changes with N , Hurst considered tossing k coins N times, and defined the random variable X_t as the difference between the number of heads and tails in the t -th experiment. For this process $R(N) = (\frac{\pi}{2}kN)^{1/2} - 1$; $S = k^{1/2}$, that is $R^*(N) = \frac{R(N)}{S(N)} \propto (\frac{\pi}{2}N)^{1/2}$ (Eqs. 3a, b, c; Korvin 1992: 329). Hurst analyzed some 120 geophysical and economic time series (river discharges, rainfall, water level, temperature, wheat prices, etc.; see Korvin 1992, for modern examples Hamed 2007) and found that R/S approximately scales as $R^*(N) = \frac{R(N)}{S(N)} \propto N^H$ (Eq. 4), where the exponent H always lied in the range $H = 0.73 \pm 0.09$, that is, significantly differed from the theoretically expected $H = 1/2$. Later, the exponent H was called *Hurst exponent*, the non-trivial scaling with exponents $H \neq 1/2$ is the *Hurst phenomenon* or *Hurst effect*, and the determination of H is the task of the *Rescaled Range* (R/S) analysis.

Random Processes with Hurst Exponent $H \neq 1/2$

As seen (Eq. 3c), the expected *Rescaled Range* of a sequence $\{X_t\}$, $t = 1, \dots, N$, of $N \gg 1$ random coin-tossing grows as $E[R^*(N)] = E\left[\frac{R(N)}{S(N)}\right] \propto (\frac{\pi}{2}N)^{1/2}$ (Eq. 4), this also holds asymptotically for any sequence of *identically and independently distributed (iid) normal variables* $E\left(\frac{R}{S}\right) = \sqrt{\frac{\pi}{2}}N^{0.5}$ (Korvin 1992: 329). Anis and Lloyd (1976) expressed the *exact* expected value of the rescaled range for *iid* normal vari-

$$\text{ables as } E\left[\frac{R(n)}{S(n)}\right] = \begin{cases} \frac{\Gamma\left(\frac{n-1}{2}\right)}{\sqrt{\pi}\Gamma\left(\frac{n}{2}\right)} \sum_{i=1}^{n-1} \sqrt{\frac{n-i}{i}} & \text{for } n \leq 340 \\ \frac{1}{\sqrt{n\pi}} \sum_{i=1}^{n-1} \sqrt{\frac{n-i}{i}} & \text{for } n > 340 \end{cases}$$

(Eq. 5a, b), where $\Gamma(x)$ is the gamma function. Hamed (2007) noted that substituting $x = N/2$, $a = 1/2$, $b = 0$ into the known

$$\text{relation } \lim_{x \rightarrow \infty} x^{b-a} \frac{\Gamma(x+a)}{\Gamma(x+b)} = 1 \quad \text{yields } \frac{\Gamma(n/2 - 1/2)}{\Gamma(n/2)} \approx \left(\frac{2}{n}\right)^{1/2}$$

(Eq. 6a) in the first factor in the right-hand side of

Eq. (5a) and, while $\sum_{r=1}^{N-1} \sqrt{\frac{N-r}{r}} \sim \frac{\pi N}{2}$ for $N \gg 1$, for small values

of N the expression $\sum_{r=1}^{N-1} \sqrt{\frac{N-r}{r}} \approx \frac{\pi N}{2} - 1.46N^{0.5}$ (Eq. 6b) gives

better approximation. Substituting Eqs. (6 a, b) to Eq. (5), Hamed got the improved estimate $E\left(\frac{R}{S}\right) \approx \sqrt{\frac{\pi}{2}}n^{0.5} - 1.164$ (Eq. 7).

There have been many speculations about what kind of processes exhibit the anomalous scaling $R/S \propto N^H$ with $H \neq 1/2$ (Korvin 1992). A feasible model is the *fractional Brownian noise (fBn)* model of Mandelbrot and Van Ness (1968). They defined first *fractional Brownian motion (fBm)* of Hurst exponent H which is a *non-stationary self-affine random process* $B_H(t) = \frac{1}{\Gamma(H+0.5)} \left\{ \int_{-\infty}^0 [t-l]^{H-0.5} - [l]^{H-0.5} \right\} dB(l) + \int_0^t [t-l]^{H-0.5} dB(l)$ (Eq. 8a)

where $B(t)$ is a Gaussian process with zero mean and σ^2 variance, and proved that the continuous-time process $B_H(t)$ satisfies: (i) its increments are stationary; (ii) $B_H(t)$ is Gaussian, $\langle B_H(t) \rangle = 0$; $\langle [B_H(1)]^2 \rangle = \sigma^2$ (Eq. 8b); (iii) $B_H(t)$ is statistically invariant (*self-affine*) under the transformation $\{\tau \rightarrow \lambda\tau; B_H \rightarrow \lambda^H B_H\}$ (Eq. 8c). Self-affinity implies that $B_H(\lambda t) - B_H(0) = \lambda^H \{B_H(t) - B_H(0)\}$ (Eq. 8d). (The process $B_{0.5}(t)$ is the ordinary *Brownian motion*). It is easy to prove that $\langle [B_H(\tau + T) - B_H(\tau)]^2 \rangle \propto \sigma^2 T^{2H}$ (Eq. 9). Next, they constructed the process $X_t^{(H)}$ from the increments of $B_H(t)$, as $X_t^{(H)} = B_H(t) - B_H(t-1)$ (Eq. 10) and called it *fractional Brownian noise (fBn)* with exponent H (Mandelbrot and Van Ness 1968), it is stationary, of zero mean and variance σ^2 . By simple algebra (using Eqs. 8 and 9) the correlation between $X_1^{(H)}$ and $X_K^{(H)}$ is: $\langle X_1^{(H)} \cdot X_K^{(H)} \rangle \propto \sigma^2 H(2H-1)K^{2H-2}$ if $K \gg 1$ and $H \neq 1/2$ (Eq. 11a); and $\langle X_1^{(H)} \cdot X_K^{(H)} \rangle = 0$ for $\forall K \neq 1$ if $H = 1/2$ (Eq. 11b). In Eq. (11a) the correlations are always positive, and fall off as a power of K . Equation (11b) (for $H = 1/2$) describes the *uncorrelated white noise*. Let us prove that $\{X_t\} = \{X_t^{(H)}\}$ satisfies Hurst's Law, $\frac{R(N)}{S(N)} \propto N^H$. If for a process $\{X_i\}$ we denote by $X^*(t)$ the partial

sum $\sum_{i=1}^t X_i$, then the range of $\{X_i\}$ can be re-written in terms of $X^*(t)$ as $R(N) = \left\{ \max_{0 \leq t \leq N} - \min_{0 \leq t \leq N} \right\} [X^*(t) - \frac{t}{N} X^*(N)]$ (Eq. 12).

In particular, for the process $\{X_t^{(H)}\}$, Eq. (10) implies that $X^{*(H)}(t) = B_H(t)$ (Eq. 13). By the affine property, Eq. (8), changing the variable t to $\tau = t/N$ in Eq. (12), we obtain $R(N) =$

$$\left\{ \max_{0 \leq \tau \leq N} - \min_{0 \leq \tau \leq N} \right\} [N^H B_H(\tau) - \tau N^H B_H(1)] = \text{const} \cdot N^H,$$

and because $S(N) \propto \sigma$ for the *fBn* $\{X_i\}$, Hurst's rule $\frac{R(N)}{S(N)} \propto N^H$ (Eq. 14) holds indeed.

The Hurst Exponent H as an Indicator of Long-Term Behavior

Let $Z(x)$ be an fBm function which is only known at the two endpoints $x = 0$ and $x = L$ of an interval $[0, L]$, and suppose we need to estimate $Z(x)$ inside the interval $0 \leq x \leq L$ (“interpolation”) and for values $L \leq x$ (“extrapolation,” “prediction”) using the *optimal unbiased linear combination* $Z(x) = \lambda_1 Z(0) + \lambda_2 Z(L)$ (Mandelbrot and Van Ness 1968 Hewett 1986 Korvin 1992: 336–337). The coefficients λ_1 & λ_2 are found from the system

$$\left. \begin{aligned} \lambda_2 \gamma(0, L) + \mu &= \gamma(0, x) \\ \lambda_1 \gamma(0, L) + \mu &= \gamma(L, x) \\ \lambda_1 + \lambda_2 &= 1 \end{aligned} \right\} \text{ (Eq. 15), where } \mu$$

is a *Lagrange parameter*, and $\gamma(x, y) = \frac{1}{2} \langle |Z(x) - Z(y)|^2 \rangle$ the *semivariogram*. By Eq. (9) for an fBm with Hurst exponent H and variance σ^2 we have $\gamma(x, y) = \frac{1}{2} \sigma^2 |x - y|^{2H}$ (Eq. 16), the system of Eq. (15) is easily solved and yields the interpolation-extrapolation formula $Z^*(x) = Z(L) \times \left\{ \frac{1}{2} [1 - |1 - \xi|^{2H} + \xi^{2H}] \right\} = Z(L) \cdot Q(\xi)$, where $\xi = \frac{x}{L}$ (Eq. 17).

The extrapolation-interpolation function $Q(\xi)$ is shown in Fig. 1 for different values of H . We have $Q(0) = 0$, $Q(1) = 1$, for $0 \leq \xi \leq 1$ the function is almost linear. For $\xi > 1$, note that $|1 - \xi| = (\xi - 1)$ and $\xi^{2H} - (\xi - 1)^{2H} \approx \frac{d}{d\xi} \xi^{2H} \sim \xi^{2H-1}$ that is for $x > L$ the function $Z(x)$ is expected to continue as $Z(x) \propto Z(L) \cdot \left(\frac{x}{L}\right)^{2H-1}$ (Eq. 18). For $H = 1/2$ the best prediction is the last functional value; for $H > 1/2$ the trend over the interval will be continued (“persistence”), for $H < 1/2$ the trend will be reversed and the predicted value tends to the mean over the interval $[0, L]$ (“antipersistence”).

Rescaled Range Analysis, Fig. 1 The interpolation-extrapolation function $Q(\xi) = Q(x/L)$ for different values of H . (From Korvin (1992: 337, Fig. 5.3, after Hewett 1986))

Traditional R/S Analysis

Rescaled Range (R/S) analysis is used to find H for a time-series. It was invented and widely applied by Hurst (1951) and, in its classic form, consists of the following steps (Korvin 1992). (i) A time series of length $N \gg 1$ is divided into a great number of shorter sub-intervals of respective lengths $n = n_1, n_2, n_3, \dots$ where $n_1 = N > n_2 \geq n_3 \geq \dots$ (Eq. 19a). One way to do this is to select, in turn, $n = N, N/2, N/4, \dots$ or, more generally, $n = N, N/v, N/v^2, \dots$ (Eq. 19b); (ii) for a partial time series X of length n ; $\{x_1, x_2, \dots, x_n\}$ we calculate its mean: $\mu = \frac{1}{n} \sum_{i=1}^n x_i$ and (iii) subtract it from all data to get *mean-adjusted values* $y_i = x_i - \mu$ ($i = 1, 2, \dots, n$); (iv) we compute the cumulative sums $Z_t = \sum_{i=0}^t y_i$ ($t = 1, 2, \dots, n$); (v) calculate the range $R(n) = \max(Z_1, Z_2, \dots, Z_n) - \min(Z_1, Z_2, \dots, Z_n)$; (vi) determine the *Standard Deviation* $S(n) = \sqrt{\frac{1}{n} \sum_{i=1}^n y_i^2}$; (vi) The process is repeated for each sub-period having the same length n , yielding the average rescaled ranges $\left\langle \frac{R(n)}{S(n)} \right\rangle$ over all sub-intervals of length n . (vii) The *Hurst exponent* is estimated by fitting the power law $\left\langle \frac{R(n)}{S(n)} \right\rangle = C \cdot n^H$ (Eq. 20) to the data. Least squares regression on the logarithms of each side of Eq. (20) yields $\log \frac{R(n)}{S(n)} \approx \log C + H \log n$ (Eq. 21a), the sign “ $\approx$ ” of approximate equality refers to the problematic issues and inevitable errors of logarithmic fitting. (viii) If the lengths of subintervals are powers of some integer v , as in Eq. (19b), it is recommended (Kriřtoufek 2010) to use base- v logarithm, that is $\log_v \frac{R(n)}{S(n)} \approx \log_v C + H \log_v n$ (Eq. 21b).

Recent Improvements and Variants

Detrended Hurst Analysis

Detrended Hurst analysis, also called *Detrended Fluctuation Analysis* DFA (Bassingthwaighte and Raymond 1994; Kriřtoufek 2010) uses a different measure of dispersion – *squared fluctuations* around the *trend of the signal*, rather than around the local mean, as in ordinary R/S analysis. Because we de-trend the sub-periods, the method works for non-stationary time-series, contrary to R/S. The procedure is labeled DFA-0, DFA-1, and DFA-2 according to the order of polynomials fitting the trend. The polynomials are seldom higher than second order (Kriřtoufek 2010).

The procedure starts as in R/S: the whole series is divided into sub-periods of length v (with increasing lengths v), then for each subperiod $\Pi_i = \{\xi_1, \dots, \xi_v\}$ a polynomial fit $P_{v,l}^{(i)}(t)$ is established (where l is the order of the polynomial, v the

length of the sub-period). The *de-trended signal* $Y_{v,l}^{(i)}(t) = \xi_t - P_{v,l}^{(i)}(t); t = 1, 2, \dots, v$ (Eq. 22) has a *fluctuation* $F_{(i)}^2(v, l) = \frac{1}{v} \sum_{t=1}^v \left(Y_{v,l}^{(i)}(t)\right)^2$ (Eq. 23). We do not divide the fluctuations by the variance but take their average over all subperiods Π_i of length v , in order to get $F_{DFA}^2(v, l)$, which scales as $F_{DFA}^2(v, l) \sim v^{2H(l)}$ (Eq. 24). The argument “ l ” in the estimated H indicates that it might depend on the degree of the fitting polynomial. Finally, an ordinary least squares regression on the logarithms of both sides of Eq. (24) yields $H(l)$ as slope of the straight line $\log F_{DFA}(v, l) \approx \log c + H(l) \log v$ (Eq. 25).

The Structure Function Method

The *Structure Function Method* utilizes that the q th-order structure functions $S_q(\tau) = \langle |W(t_i + \tau) - W(t_i)|^q \rangle$ of processes $W(t)$ showing the Hurst effect scale as $S_q(\tau) \sim C_q \cdot \tau^{qH(q)}$ (Eq. 26). The exponent $H(q)$ is determined by plotting $S_q(\tau)$ vs. τ on a log-log plot, and finding the slope $qH(q)$. Gilmore et al. (2002), in their analysis of *plasma turbulence*, eliminated the effect of q on $H(q)$ by using $q = 0.5, 1.0, 1.5, \dots, 5.0$ and averaging the $H(q)$ exponents.

A Modified Scaling Law

Hamed (2007) noted that traditional R/S analysis gives biased estimates of the Hurst exponent for finite samples, and more precisely computed the exact expression of Anis and Lloyd (1976) for the expected rescaled range of independent normal summands,

$$E\left[\frac{R(n)}{S(n)}\right] = \begin{cases} \frac{\Gamma\left(\frac{n-1}{2}\right)}{\sqrt{\pi}\Gamma\left(\frac{n}{2}\right)} \sum_{i=1}^{n-1} \sqrt{\frac{n-i}{i}} & \text{for } n \leq 340 \\ \frac{1}{\sqrt{n\pi}} \sum_{i=1}^{n-1} \sqrt{\frac{n-i}{i}} & \text{for } n > 340 \end{cases}.$$

He derived, instead of the customary asymptotic formula $E\left(\frac{R}{S}\right) = \sqrt{\frac{\pi}{2}} N^{0.5}$, an improved scaling law $E\left(\frac{R}{S}\right) \approx \sqrt{\frac{\pi}{2}} n N^{0.5} - 1.164$. Inspired by this equation, he proposed the $\frac{R(n)}{S(n)}$ data should be non-linearly fitted as $E\left(\frac{R(n)}{S(n)}\right) = an^H + b$ (Eq. 27). He applied this to a large set of data and found: (a) For the annual mean temperature data from 56 Historical Climatological Network (HCN) stations in Midwest USA the proposed estimator gave an average estimated Hurst coefficient 0.645 compared to 0.725 with the old method (−11% change); (b) for annual rainfall data from 60 HCN stations in Midwest USA it gave $H = 0.568$ instead 0.650 (−13% change); (c) for annual river flow data from 49 U.S. Geological Survey (USGS) river stations in Midwest USA $H = 0.631$ as compared to 0.621 (+2% change); for tree-ring data from

88 locations over the world $H = 0.596$ increased to 0.639 (+7% change).

Anis-Lloyd Corrected R/S Hurst Exponent

Anis and Lloyd (1976) derived different theoretical expressions for the expected rescaled range of independent normal summands for small and large values of n :

$$E\left[\frac{R(n)}{S(n)}\right] = \begin{cases} \frac{\Gamma\left(\frac{n-1}{2}\right)}{\sqrt{\pi}\Gamma\left(\frac{n}{2}\right)} \sum_{i=1}^{n-1} \sqrt{\frac{n-i}{i}} & \text{for } n \leq 340 \\ \frac{1}{\sqrt{n\pi}} \sum_{i=1}^{n-1} \sqrt{\frac{n-i}{i}} & \text{for } n > 340 \end{cases}.$$

The *Anis-Lloyd corrected R/S Hurst exponent* is calculated as 0.5 plus the slope of $\frac{R(n)}{S(n)} - E\left[\frac{R(n)}{S(n)}\right]$. A slight modification of the original Anis-Lloyd formula by a factor $(n - 1/2)/n$,

$$E\left[\frac{R(n)}{S(n)}\right] = \begin{cases} \frac{n-1/2}{n} \cdot \frac{\Gamma\left(\frac{n-1}{2}\right)}{\sqrt{\pi}\Gamma\left(\frac{n}{2}\right)} \sum_{i=1}^{n-1} \sqrt{\frac{n-i}{i}} & \text{for } n \leq 340 \\ \frac{n-1/2}{n} \cdot \frac{1}{\sqrt{n\pi}} \sum_{i=1}^{n-1} \sqrt{\frac{n-i}{i}} & \text{for } n > 340 \end{cases} \quad (\text{Eq. 28})$$

gives further improvements for small n (Weron 2002).

Estimating H from the Power Spectrum

The method (Weron 2002) utilizes that (by Eq. 11) an fBn with exponent H has a power spectrum $G(f) \propto f^{-2H+1} = f^{-\beta}$ (Eq. 29) with $\beta = 2H - 1$ (Eq. 30) (see Korvin 1992: 341, Eq. 5.1.2.2), f is frequency. If $P(f)$ is power spectrum of a fractal process, its Hurst exponent H is obtained from the $\log P(f)$ versus $\log f$ plot. A straight line with a negative slope ($-\beta$) is obtained for a *self-affine* process, and the Hurst exponent is found as $H = (\beta + 1)/2$ (Eq. 31).

A nice example is Hewett's study (1986; Korvin 1992: 333, 335) who analyzed the *porosity values* derived from a *gamma-gamma* (“density”) log through 1000 feet of sandstone (Fig. 2a). R/S analysis of the porosity log resulted in $H = 0.85$. As an independent check, Hewett computed the power spectrum of the log, established a fall-off with frequency $\propto f^{-\beta}$, with $\beta = 0.71 \approx 2H - 1$. Note that the relation (Eq. 31) had been rigorously proved for fBn processes only (Mandelbrot and Van Ness 1968), and is not necessarily valid for an arbitrary time series.

Rescaled Range Analysis, Fig. 2 (a) Density-derived porosity log through a sandstone formation, depth in feet; (b) its R/S analysis, dashed line shows the $H = 2$ case. (From Korvin (1992: 333, Fig. 5.2 d1 and d2, after Hewett 1986))

Periodogram Regression

This is another spectral method which estimates the so-called *fractional differencing parameter* d from the *periodogram*, and from the relation $H = d + 0.5$ (Eq. 32) established for a fractional Gaussian noise with Hurst exponent H , gets H (Weron 2002). For the data $\{X_1, X_2, \dots, X_L\}$ the *periodogram* (analogue of the *spectral density* for sampled data) is computed as $P_L(\omega_k) = \frac{1}{L} \left| \sum_{t=1}^L x_t \cdot e^{-2\pi j(t-1)\omega_k} \right|^2$; $j = \sqrt{-1}$; $\omega_k = \frac{k}{L}$; $k = 1, \dots, L/2$ (Eq. 33), then we run a linear regression $\log[P_L(\omega_k)] \approx a - d \cdot \log\{4\sin^2(\omega_k/2)\}$ (Eq. 34) at sufficiently low frequencies ω_k , $k = 1, 2, \dots, K \leq L/2$ (Eq. 35) for which the logarithmic slope is approximately linear. The choice of K in Eq. (35) is crucial, in practice $L^{0.2} \leq K \leq L^{0.5}$. Apparently, this is the only method with known *asymptotic properties* for finding H (Weron 2002: 289).

Practical Issues

There is a consensus among practitioners (Bassingthwaight and Raymond 1994; Gilmore et al. 2002; Hamed 2007; Křišťoufek 2010) that if the data is of short duration, contains gaps or bursts of noises, or it is non-stationary, then the calculation of the H by R/S analysis is not reliable. When tested on computer-generated fBn signals of known H it has been found that R/S gives biased estimates of H : too low for $H > 0.72$, and too high for $H < 0.72$, and the method has poor convergence properties, it requires about 2000 points for 5% accuracy and 200 points for 10% accuracy (Bassingthwaight and Raymond 1994). According to Gilmore et al. (2002), the R/S method accurately determines

H in plasma fluctuation data provided a long enough record is used, but lags must be greater than five to ten times the *autocorrelation time* τ_L . They claim the *structure function* only requires lags $\tau \geq 1 \times \tau_L$. (For a random process $X(t)$ the *autocorrelation time* is the lag where the autocorrelation function falls off to $(1/e)$ -times its peak value, $|R_{XX}(\tau)| \leq \frac{1}{e} R_{XX}(0)$ for $\forall \tau \geq \tau_L$)

Is it important to remove *local trends* in R/S analysis? Hurst (1951) himself applied trend correction. Bassingthwaight and Raymond (1994), who tested the performance of R/S analysis on *fractional Brownian noise* of known H , reported that the locally trend-corrected method gives better estimates of H when $H \geq 0.5$, that is, for persistent signals with positive correlations between neighboring values.

Concluding Remarks

Since introduced by Hurst (1951), *Rescaled Range (R/S) Analysis* has been used to find long-term dependence in hydrologic and geophysical records and other real-world data. R/S Analysis provides the *Hurst exponent* which characterizes long-term correlations in stochastic processes. There are persistent ($H > 0.5$) and antipersistent ($H < 0.5$) processes, for the white noise $H = 0.5$. Natural processes with Hurst exponent H can be modeled by *fractional Brownian noise (fBn)* of Hurst exponent H . There are many variants of R/S Analysis, here we discussed (i) *Traditional R/S analysis*; (ii) *Detrended Fluctuation Analysis DFA*; (iii) a *modified scaling law*; (iv) the *Anis-Lloyd corrected R/S Hurst exponent*; (v) *Estimating H from the power spectrum*; (vi) *Periodogram regression*. To find their relative merits,

speed up their convergence, and determine their asymptotic properties need future research.

Biography

Richard Arthur Reyment (1926–2016) was born in Coburg, a suburb of Melbourne, Australia, in a family with roots in England, Ireland, Sweden, and Spain. After obtaining his B.Sc. from the University of Melbourne in 1948, he emigrated to Sweden. He started his scientific career as a geologist at the Geological Survey of Nigeria (1950–1956), followed by a senior lectureship at Stockholm University, Sweden (1956–1962). He was then appointed Professor of Petroleum Geology at the University of Ibadan, Nigeria (1963–1965), Associate Professor of Biometry at Stockholm University (1965–1967), and finally Professor and Chair of Historical Geology and Palaeontology at Uppsala University, Sweden (1967–1991). After retirement, he continued his research as Emeritus Professor at the Swedish Museum of Natural History in Stockholm.

In 1955 Reyment obtained his M.Sc. from the University of Melbourne on the subject of Cretaceous mollusks of Nigeria and shortly thereafter his Ph.D. from Stockholm University on the stratigraphy and palaeontology of the Cretaceous of Nigeria and the Cameroons. During his time as senior

lecturer at Stockholm University, his research focused mainly on micropalaeontology. In 1958/59 the Finnish palaeontologist Björn Kurtén visited Stockholm and introduced him to the use of statistical methods. This marked the beginning of what was to become his major field of research, biometric applications in palaeontology and related sciences. In 1960/61 he spent a period as research associate in the Soviet Union, where he was influenced by Andrei Borisovich Vistelius, generally regarded as the founder of the science of mathematical geology. In 1966/67 he spent a period at the Kansas Geological Survey (University of Kansas), USA, an institution with a strong record in quantitative geology, for example, through Robert R. Sokal, Daniel F. Merriam, F. James Rohlf, and Roger L. Kaesler.

In the mid-1960s Reymont headed the Subcommittee for the Application of Biometrics in Paleontology of the International Paleontological Union, and from 1968 to 1974 he was a member of the IUGS Committee on Storage, Automatic Processing and Retrieval of Geological Data (COGEODATA). At the 1968 International Geological Congress in Prague, the International Association for Mathematical Geology (IAMG) was born, with Reymont as prime mover. He was the first Secretary General of the Association 1968–1972 and President 1972–1976. Together with Daniel F. Merriam he founded the journal *Computers & Geosciences*, launched in 1975.

In 1967 Reymont was appointed to the Chair of Historical Geology and Palaeontology at Uppsala University. Besides teaching and supervising students, he continued his research and carried out extensive fieldwork. Important achievements during his Uppsala years were the IGCP Project “Mid-Cretaceous Events” and the launch of the journal *Cretaceous Research*.

Reymont was a highly versatile scientist. He published articles and books on several fossil groups (mainly ammonites, ostracods, and foraminifers), regional geology, stratigraphy, biogeography, dispersal of organisms, palaeoecology, evolution, sexual dimorphism, actuopalaeontology, sedimentology, random events in time (volcanic eruptions and earthquakes), geomagnetism, geochemistry, and history of geology. The majority of his publications concerned the Jurassic, Cretaceous, or Tertiary. Other publications dealt with mathematical methods and topics outside the geosciences, such as biology, biochemistry, genetics, serological analysis, linguistics, Romanis, and Spanish Moors. Remarkably enough, he also found time for his many hobbies and interests, such as music (clarinet and oboe), squash and tennis, family genealogy, history, and, not least, languages. He spoke fluent English, Swedish, French, German, and Spanish and had a good reading knowledge of Latin, Portuguese, Russian, and Afrikaans. He also studied Japanese, Yoruba, Finnish, and Romani.

Reymont was an influential pioneer in the application of mathematical methods in the geosciences. His impact is reflected in the numerous citations in the *Dictionary of Mathematical Geosciences* (Howarth 2017), found under the topics *asymmetry analysis*, *biostratigraphic zonation*, *biplot*, *canonical correlation*, *cross-validation*, *discriminant analysis*, *eigenanalysis*, *heteroscedacity*, *kurtosis*, *latent root*, *morphometrics*, *multivariate normal distribution*, *pattern classification*, *peakedness*, *point event*, *point process*, *positive definite matrix*, *principal component analysis*, *quantitative paleoecology*, *robust estimate*, *scores*, *serial correlation coefficient*, *singular value*, *slotting*, *statistical zap*, *survival function*, and *zap*. For additional information about Richard Reymont's activities and achievements, see Birks (1985), Merriam (2004), Merriam and Howarth (2004), Howarth (2017), and Sagar et al. (2018), and Bengtson (2018) for a general biography including a list of his publications.

R-Mode Factor Analysis

Norman MacLeod

Department of Earth Sciences and Engineering, Nanjing University, Nanjing, Jiangsu, China

Definition

R-Mode Factor Analysis – a statistical modeling procedure whose purpose is to find a small set of latent linear variables that estimate the influence of the factors controlling the inter-variable covariance or correlation structure in a multivariate dataset and are optimized to preserve as much of that structure as appropriate given an estimate of the number of causal influences.

R-Mode Factor Analysis, Table 1 Correlation matrix of academic test scores that exhibit a classic factor structure. (From Manly 1994)

	Classics	French	English	Mathematics	Music
Classics	1.00	0.83	0.78	0.70	0.63
French	0.83	1.00	0.67	0.67	0.57
English	0.78	0.67	1.00	0.64	0.51
Mathematics	0.70	0.67	0.64	1.00	0.51
Music	0.63	0.57	0.51	0.51	1.00

Introduction

Factor analysis (FA) is often regarded as a simple variant of principal components analysis (PCA). Indeed, in some quarters, FA has a somewhat nefarious reputation due to the nature of its statistical model and due to its overenthusiastic use in the field of psychology, especially the branch that deals with intelligence testing (see Gould 1981).

Historical Background

Around 1900 Charles Spearman noticed that scores on different academic subject tests often exhibited an intriguing regularity. Consider the following correlation matrix of test scores (Table 1).

If the diagonal values are ignored, in many cases the ratio between paired variable values approximates a constant. Thus, for English and Mathematics . . .

$0.78/0.70 = 1.114$	$0.67/0.67 = 1.000$	$0.51/0.51 = 1.000$
---------------------	---------------------	---------------------

. . . and for French and Music . . .

$0.83/0.63 = 1.317$	$0.67/0.51 = 1.314$	$0.67/0.51 = 1.314$
---------------------	---------------------	---------------------

Spearman (1904) suggested the most appropriate model for such data had the following generalized form.

$$X_j = a_{j,1}F_1 + e_j \quad (1)$$

In this expression, a_j was a standardized score the j^{th} test, F was a “factor” value for the individual taking the battery of tests, and e_j was the part of X_j specific to each test. Because Spearman was dealing with the matrix of correlations, both X and F were standardized, with means of zero and standard deviations of one. This fact was taken advantage of in Spearman’s other FA insight, that a_j^2 is the proportion of the variance accounted for by the factor.

Using these relations Spearman proposed that mental abilities could be deduced from the scores on a battery of different tests and were composed of two parts, one (F) that was common to all tests and so reflected the innate abilities – or “general intelligence” – and one (e) that was specific to each test and so could be interpreted as evidence of subject-specific

aptitude, culture-based bias in the test, or some combination of the two.¹ Generalizing the relations presented above, the model underlying FA has the following form.

$$\begin{aligned} X_1 &= a_{1,1}F_1 + a_{1,2}F_2 \cdots + a_{1,m}F_m + e_1 \\ X_2 &= a_{2,1}F_1 + a_{2,2}F_2 \cdots + a_{2,m}F_m + e_2 \\ X_3 &= a_{3,1}F_1 + a_{3,2}F_2 \cdots + a_{3,m}F_m + e_3 \\ &\vdots \\ X_j &= a_{j,1}F_1 + a_{j,2}F_2 \cdots + a_{j,m}F_m + e_j \end{aligned} \quad (2)$$

In this expression, a_j is a standardized value the j^{th} variable, F is the “factor” value for that variable across all measured or observed cases, and e_j is the part of the correlation not accounted for by the factor structure. *R*-mode factor analysis attempts to find a set of m linear factors (F , where $m < j$) that underly the expression of the sample’s covariance or correlation structure; hopefully one that provides a good estimate of the larger population’s structure from which the sample was drawn.

Note the similarity between this model and the multiple regression analysis model. The creators of factor analysis viewed it originally as a type of multiple regression analysis. But unlike a standard regression problem in which a set of observations (x) is related to an underlying general model (y) by specifying a rate of change (the slope β), one cannot observe any aspect of the factor(s) (F) directly. As a result, their structure must be inferred from the raw data, which represents an unknown mixture of common and unique variances.

Standard PCA also cannot resolve this problem. The PCA model is simply a transformation that re-expresses the observed data in a form that maximizes variance on the various eigenvectors and ensures their orientational independence from one another. This approach focuses on accounting for variance and keeps extracting vectors until the remaining unaccounted – or residual – variance is either exhausted or drops below some arbitrarily determined threshold. Factor analysis does not try to account for the variable variance

¹This seemingly straight-forward interpretation of Spearman’s work later became highly controversial when estimates of a person’s general intelligence were used to direct or limit their life opportunities and when the culturally biased character of many standard ‘intelligence’ tests was recognized (see Gould 1981 for a review).

values exhibited by a sample, but instead focuses on recovering the structure of the covariances or correlations among the variables. In other words, PCA attempts to reduce the residual values of the diagonal or trace of the covariance or correlation matrix. Factor analysis attempts to model the covariances or correlations in such a way as to minimize the residual values of the matrix's off-diagonal elements.

Among the many myths about FA is the idea that it only differs from PCA in the sense that the number of factors extracted from the covariance or correlation matrix in FA is less than the number of variables, whereas in PCA, the number of components extracted equals the number of variables. Nothing could be further from the truth. The principal use of PCA is to reduce the dimensionality of a dataset from p variables to m components, where $p < m$. Factor analysis attempts to infer both the number and the effects of the influences responsible for the variance structure. The erroneous view of equivalence in the relation between PCA and FA has been perpetuated by the innumerable over-generalized and/or superficial descriptions of both techniques, especially in the user's guides of commercial multivariate data-analysis software packages in which these methods are often discussed together owing to the use of eigenanalysis (or singular value decomposition) in their calculation.

Choosing and Extracting the Factors

There are a number of ways to perform a classic *R*-mode FA. The method presented below would not be accepted by many as "true" FA; especially as it is practiced in the social sciences. However, I will recount a basic version of the component-based procedure referred to as FA by most earth scientists (e.g., Jöreskog et al. 1976; Reymont and Jöreskog 1993; Manly 1994; Davis 2002).

Factor analysis begins with a PCA. In addition to a set of data, FA assumes the researcher has a level of understanding of the processes responsible for the data's variance structure sufficient to estimate how many independent factors are involved. This number is required as a controlling parameter.

In Spearman's case, he suspected a one-factor solution, the one-factor model quantifying his "general intelligence" index with the remaining test-specific variation being subsumed into the error term. For morphological data (see MacLeod

2005 for an example) where distance measurements have been collected from a set of fossil morphologies, the generalized factors might refer to "size" and "shape." Regardless of the number of factors specified, all applications of FA assume the existence of both "generalized effect" factors and a specific-effect deviation.

It is often the case that one has little idea beforehand how many factors are either present, or of interest, in the data. Fortunately, FA, like PCA, can be used in an exploratory mode. There are a number of FA rules-or-thumb that can be of assistance in making decisions regarding how many factors axes to specify.

If you are working with a correlation matrix, one of the most popular and easiest to remember is to set the number of factors to equal the number of PC eigenvectors that contain more information than the raw variables. This makes sense in that these axes are easy to identify (all will have eigenvalues >1.0) and there seems little logical reason to consider composite variables that contain less information than their raw counterparts. Another popular rule-of thumb is the so-called scree test in which the magnitudes of the eigenvalues are plotted in rank order and the decision made on the basis of where the slope of the resulting curve breaks from being dominantly vertical to dominantly horizontal. The other quick and easy test to apply when considering how many factors to extract, and indeed, whether factor analysis is appropriate, is Spearman's constant proportion test (see above). If a large number of the ratios between the non-diagonal row values of the correlation matrix do approximate a constant, the data exhibit the classic structure assumed by the factor analysis model and the appropriate number of factors will be the number of approximately constant values. Regardless, it is important to remember that, if there is uncertainty regarding the number of factors controlling the dataset's variance structure, FA may proceed but should be interpreted with caution.

Unlike classical PCA, factor analysis scales the loadings of the retained components by their eigenvalues, according to the following expression.

$$a_{j,m} = \sqrt[2]{\lambda_m} b_{j,m}. \quad (3)$$

Here, λ_m is the eigenvalue associated with the m^{th} principal component with m being set to the number of retained factors

R-Mode Factor Analysis, Table 2 Principal component loadings, factor loadings, and factor communalities for the example trilobite morphometric variables

Parameter/variable	Principal components			Factors		
	1	2	3	1	2	Communality
Eigenvalue	2.776 (92.54%)	0.142 (4.72%)	0.082 (2.74%)	2.776 (92.54%)	0.142 (4.72%)	
Body length	0.573	0.757	-0.314	0.954	0.285	0.992
Glabella length	0.583	-0.108	0.805	0.972	-0.041	0.947
Glabella width	0.576	-0.644	-0.504	0.959	-0.242	0.979

and b is the eigenvector loading of the j^{th} variable on the m^{th} principal component. This scaling, along with the reduction in the number of components (= factors) being considered, represents a basic computational difference between PCA and FA.

Next, the “communality” values of the m scaled factors are calculated as the sum of squares of the factor loading values. This summarizes the proportion of variance provided by those variables to each factor. The quantity “1- the sum of communality values for each variable” then expresses the proportion of the variable’s variance attributable to the error term (e) of the factor model. If the correct number of factors has been chosen, all the summed, squared factor values should exhibit a high communality on each variable with a low residual error.

Once the factor equations have been determined, the original data can be projected into the factor space. The resulting

factor scores ($\hat{X}$) may then be tabulated, plotted, inspected, and interpreted in the manner normal for PCA ordinations. Table 2 and Fig. 1 compare and contrast results of a PCA and two-factor FA for the trilobite data listed in MacLeod (2005).

For this simple dataset, both the first principal component and first factor would be interpreted as being consistent with generalized (allometric) size variation owing to their uniformly positive loading coefficients of varying magnitudes. Similarly, for both analyses, the second component/factor would be interpreted as a localized shape factor owing to the contrast between body length and the glabella variables. While the relative positions of the projected data points are also similar, and discontinuities in the gross form distributions are evident in both plots, the scaling of the PCA and FA axes differs reflecting the additional eigenvalue-based scaling that is part of component-based FA. Nevertheless, an important change has taken place in the ability of the FA vectors to

R-Mode Factor Analysis, Fig. 1 Ordination spaces formed by the first two principal components (a) and a two-factor extraction (b) from the three-variable trilobite dataset. Note the similarity of these results in

terms of the relative positions of forms projected into the PCA and factor spaces and the difference in terms of the axis scales

R-Mode Factor Analysis, Table 3 Original correlation matrix, correlation matrix reproduced on the basis of the first to principal components, and correlation matrix reproduced by the two-factor FA solution. Note

the bottom two matrices are based on the component/loading values shown in Table 2

Original correlation matrix			
	Body length	Glabella length	Glabella width
Body length	1.000	0.895	0.859
Glabella length	0.895	1.000	0.909
Glabella width	0.859	0.909	1.000
Reproduced correlation matrix (PCA)			
Body length	0.902	0.253	−0.158
Glabella length	0.253	0.352	0.405
Glabella width	−0.158	0.405	0.746
Reproduced correlation matrix (FA)			
Body length	0.992	0.916	0.847
Glabella length	0.916	0.947	0.943
Glabella width	0.847	0.943	0.979

R-Mode Factor Analysis, Fig. 2 Original (a) and rotated (b) variable-axis orientations with respect to the fixed, orthogonal factor axis orientation for the three-variable trilobite data. The rotation of these variables is centered on Factor 1 owing to their high mutual correlations.

A summary of the (minor) projected data displacements arising as a result of varimax axis rotation (c). More complex datasets will typically exhibit larger variable-vector rotations

represent the structure of the original correlation matrix (Table 3).

Here it is evident that the two-factor PCA result focuses on reproducing the values along the trace of the original covariance/correlation matrix, whereas the FA result focuses on reproducing the entire structure of the covariance/correlation

matrix. If all three principal components had been used in these calculations, only the trace of the original correlation matrix would be reproduced exactly, whereas if a three-factor solution had been calculated, the original correlation matrix would have been reproduced exactly (except for rounding error). In this sense then, FA represents a more information-

rich analysis than PCA, especially if a dramatic reduction in dimensionality is required. The validity of applying the FA model to a dataset is predicated, however, on the dataset exhibiting a factor-based variance structure.

Factor Rotation

In addition to scaling of the factor loadings, the other aspect of a classic component-based FA that differs from standard PCA is factor rotation. As can be seen from Fig. 1, the factor-scaling calculation does not alter the orientation of the factor axes with respect to the original variable axes. However, since the goal of a FA is to “look beyond” the data to hand in order to discover the structure of the influences responsible for observed patterns of variation, strict geometric conformance between the original data and the factor model is regarded by many factor analysts as being beside the point. Thus, a justification is provided to alter the orientations of the factor axes relative to the original variable axes (or vice versa) in order to make them easier to interpret in terms of the original variables.

Two general approaches to factor rotation are popular: orthogonal (in which the orthogonality of the factor-axes system is maintained) and oblique (in which the factor axis-orthogonality constraint is relaxed). In both cases, the goal of factor rotation is to align the factor axes with the covariance/correlation structure of the variable set to the maximum extent possible. Orthogonal axis rotation (usually accomplished using Kaiser’s 1958 varimax procedure) performs this operation by iteratively changing the orientation of the factor-axis system two factors at a time until the squares of the variances are either maximized or minimized across all factors. Operationally this amounts to adjusting the set of factor loadings, rigidly in a geometric sense, until all variables exhibit loadings at or as close to 0.0 or ± 1.0 as possible. Figure 2 illustrates the unrotated and varimax rotated solutions for the example trilobite dataset.

Obviously, in this simple example, the variable vectors were already quite well aligned with factor 1. However, a small adjustment was necessary to achieve a fully optimized result. In higher-dimensional datasets, the angle of varimax-optimized factor rotation can be quite large (see Davis 2002 for an example).

A final word about calculation of the factor scores that project the original data into the space of the factor axes. The PCA method accomplishes this by postmultiplying the original data values (X) by the component loadings (A). The factor model differs from principal component model, however, in that the former subdivides the variance structure into common and unique factors (see above). Thus, true factor scores (X')

cannot be calculated in the same way as principal component scores because the data matrix contains contributions from both the common and unique factors. In order to obtain the true factor scores, the raw (or standardized) data must be normalized for the unique factor’s influence. Fortunately, this can be accomplished with minimal effort by postmultiplying the data matrix by the inverse of the covariance/correlation matrix (S^{-1}), prior to the factor loading postmultiplication.

$$\hat{X} = XS^{-1}F \quad (4)$$

Conclusion

R-mode factor analysis has a long and distinguished history in the earth sciences and has played a key data-analytic role in advancing many earth-science research programs (e.g., Jöreskog et al. 1976; Sepkoski 1981; Reyment and Jöreskog 1993). Recently, Bookstein (2017) has advocated its use in the context of general morphometric analysis as a more path-analytic approach to understanding of the influences that underly shape variation. It is to be hoped that this and (perhaps) other applications of FA in novel data-analytic contexts will lead to the wider use of FA in geological, oceanographic, biological, meteorological, and cryological contexts.

Robust Statistics

Peter Filzmoser

Institute of Statistics & Mathematical Methods in Economics,
Vienna University of Technology, Vienna, Austria

Definition

Robust statistics is concerned with the development of statistical estimators that are robust against certain model deviations, caused, for example, by outliers.

Introduction

Data analysis and robust statistics have a strong historical link, because many questions regarding specific features in the data structure are connected to the outlier problem. Outliers have always been viewed as something atypical, not represented in the data majority, and for that reason they are usually of special interest to the analyst. Robust statistics, in general, is concerned with the development of statistical estimators that are robust against certain model deviations, such as deviations from normal distribution, which is frequently assumed in estimation theory. Robust estimators are supposed to still deliver reliable results in case of such deviations, e.g., caused by outliers, and various tools that allow to quantify the robustness of an estimator have been developed (Maronna et al. 2019). Probably the most prominent tool is the *breakdown point* (BP), which refers to the smallest fraction of observations that could be replaced by any arbitrary values in order to make the estimator completely meaningless. For example, for estimating the univariate location, the commonly used arithmetic mean has a BP of zero, because already replacing a single observation by an arbitrary value can drive the estimator beyond all bounds. The median, on the other hand, achieves the maximum BP of 0.5. Under normality, however, the median comes with a lower statistical efficiency, and thus often a compromise between (positive) BP and reasonable efficiency needs to be taken (e.g., trimmed mean or, better, M estimator – see below).

This entry aims to explain some important tools and concepts in robust statistics from a practical perspective. Robust regression and covariance estimation, as well as principal component analysis (PCA) will be in focus. The interested reader can find many more details and background to robust statistics in the book Maronna et al. (2019).

Regression

Many text books on robustness motivate the use of robust regression routines by presenting some x - and y -data which follow a linear trend – with the exception of some single outliers. Those outliers, appropriately placed, are able to completely spoil the least-squares (LS) regression line but do not affect the fit from a robust regression. While such examples may be inspiring, one would always ask why the outliers are not simply removed, as they are clearly visible, and a subsequent LS regression would be useful for predicting y from x . The problem is that in more complex situations, especially in higher dimension, outlier detection is not at all trivial. Fortunately, the outlier detection step is not necessary in practice, because robust regression methods will automatically downweight outliers, thus observations which are inconsistent with the linear model, and this also works in the higher-dimensional situation.

Example Data

In order to be more specific, a data set from the GEMAS project (Reimann et al. 2014), a geochemical mapping project covering most European countries, is considered in the following. Similar as in van den Boogaart et al. (2020), a regression of pH on the composition of the major oxides Al_2O_3 , CaO , Fe_2O_3 , K_2O , MgO , MnO , Na_2O , P_2O_5 , SiO_2 , TiO_2 , and LOI is of interest. Here, only the data from Poland are used, as they are relatively homogeneous concerning the soil type. In other countries, the pH values heavily depend on whether the soils are on karstic landscapes or on felsic rocks, for instance.

Regression Model

The response, here pH, is denoted as variable y , while the explanatory variables are x_1 to x_D . In total, there are $n = 129$ samples taken from Poland, which lead to the observations y_i , and $x_{i1}, \dots, x_{iD}$, for $i = 1, \dots, n$. Since the explanatory variables are compositional data, it is advisable to first transform them into the usual Euclidean geometry for which the traditional regression methods have been designed. One option is to use pivot coordinates (Filzmoser et al. 2018), which results in the variables $z_1, \dots, z_{D-1}$, with the corresponding observations $\mathbf{z}_i = (z_{i1}, \dots, z_{i,D-1})'$. The linear regression model is

$$y_i = b_0 + \sum_{j=1}^{D-1} z_{ij}b_j + \varepsilon_i, \quad (1)$$

with the error terms ε_i , which are supposed to be independent and $N(0, \sigma^2)$ distributed, where σ^2 is the error variance. For pivot coordinates, the particular interest is in the coefficient b_1 associated to variable z_1 , which contains all relative information of x_1 to the remaining parts in the composition. A reordering of the composition, with a different part on the first position, followed by computing pivot coordinates allows for an interpretation of the coefficient related to another (first) part (Filzmoser et al. 2018). For a given estimator $\hat{\mathbf{b}} = (\hat{b}_0, \hat{b}_1, \dots, \hat{b}_{D-1})'$, one can compute the fitted values $\hat{y}_i = (1, \mathbf{z}_i')\hat{\mathbf{b}}$, and the residuals $r_i = r_i(\hat{\mathbf{b}}) = y_i - \hat{y}_i$, for $i = 1, \dots, n$, which refer to the discrepancy of the observed responses to the fitted ones.

Least-Squares (LS) Estimator

The LS estimator minimizes the sum of the squared residuals and is thus defined as

$$\hat{\mathbf{b}}_{LS} = \underset{\mathbf{b}}{\operatorname{argmin}} \sum_{i=1}^n r_i^2(\mathbf{b}). \quad (2)$$

Outliers in the context of regression may refer to atypical values in the response, or to unusual observations in the space of the explanatory variables. The former are called vertical outliers, and the latter leverage points, where a distinction between good (values along the regression hyperplane) and

bad leverage points (values far away from the regression hyperplane) is made. Vertical outliers as well as bad leverage points lead to large residuals, and their square can heavily dominate the minimization problem (Eq. 2). For this reason, $\hat{\mathbf{b}}_{LS}$ is sensitive to outliers and has a BP of zero, since even a single observation could “attract” the regression hyperplane and thus make the estimator useless for the data majority.

LS Regression for the Example

For the considered example data set, a reliable outlier detection based on visual inspection is practically impossible. Visual diagnostics is thus done only after model fitting. Figure 1 (left) shows the response values y_i versus the fitted values $\hat{y}_i$ from LS regression. The solid line indicates equality of response and fitted values, and the dashed lines refer to the outlier cutoff values for the residuals, which are typically considered as $r_i(\hat{\mathbf{b}}_{LS})/\hat{\sigma}_{LS} = \pm 2.5$, where $\hat{\sigma}_{LS}^2$ is the estimated residual variance from the LS estimator. According to these cutoff values, there are no outlying residuals, and the QQ-plot (Fig. 1, right) even confirms approximate normality of the residuals. The model does not fit well, because for small values of pH it leads to an overestimation, and for bigger values to an underestimation. At this stage, however, it is unclear if a nonlinear model would be more appropriate, if outliers could have affected the LS estimator, or if the explanatory variables are simply not more useful for modeling the response.

Robust Regression

Robustification of the LS estimator are M estimators for regression, which minimize a function, say ρ of the residuals.

Robust Statistics, Fig. 1 LS regression of pH on the composition of the major oxides. Left plot: pH versus fitted values of pH; right plot: normal QQ-plot for the LS residuals

Since this would depend on the residual scale, the M estimator is defined as

$$\hat{\mathbf{b}}_M = \underset{\mathbf{b}}{\operatorname{argmin}} \sum_{i=1}^n \rho\left(\frac{r_i(\mathbf{b})}{\hat{\sigma}}\right), \quad (3)$$

where $\hat{\sigma}$ is a robust scale estimator of the residuals (Maronna et al. 2019). If ρ is the square function, thus $\rho(r) = r^2$, one would again obtain the LS estimator. In order to achieve robustness, the function ρ thus needs to be chosen adequately: For small (absolute) residuals, it should be approximately quadratic to obtain high efficiency, while for large (absolute) residuals it needs to increase more slowly than the square. Various proposals are available in the literature, and they also affect the robustness properties of the resulting estimator. It also matters how $\hat{\sigma}$ is derived. The so-called MM estimator combines a highly robust scale estimator with an M estimator, and it achieves a BP of 0.5, with a high (tunable) efficiency (Maronna et al. 2019).

Another robust regression estimator which is probably easier to understand and still widely applied is the LTS (least trimmed squares) estimator, defined as

$$\hat{\mathbf{b}}_{LTS} = \underset{\mathbf{b}}{\operatorname{argmin}} \sum_{i=1}^h r_{(i)}^2(\mathbf{b}), \quad (4)$$

where $r_{(1)}^2 \leq \dots, r_{(h)}^2 \leq \dots \leq r_{(n)}^2$ are the ordered values of the squared residuals and h is an integer between $n/2$ and n . The maximum BP of 0.5 is attained for $h = \lfloor \frac{n+D}{2} \rfloor$, where $\lfloor a \rfloor$ is the integer part of a (Maronna et al. 2019). Based on the

residuals from the LTS estimator, it is possible to robustly estimate the residual variance by

$$\hat{\sigma}_{LTS}^2 = c \cdot \frac{1}{h} \sum_{i=1}^h r_{(i)}^2(\hat{\mathbf{b}}_{LTS}), \quad (5)$$

where c is a constant for consistency under normality.

Similar as above, residuals would be considered as outlying if

$$|r_i(\hat{\mathbf{b}}_{LTS}) / \hat{\sigma}_{LTS}| > 2.5. \quad (6)$$

In contrast to the outlier diagnostics for LS regression, both the residuals and the residual variance are estimated robustly within LTS regression, and thus, this diagnostic tool is reliable and useful in presence of outliers.

Since the statistical efficiency of the LTS estimator is low, it is common to add a reweighting step. This consists of a weighted LS estimator, with weights 0/1, where zero is assigned to residuals for which (Eq. 6) is valid, and one otherwise.

Robust Regression for the Example

Figure 2 presents the resulting plots for LTS regression, analogously as in Fig. 1 for LS regression. The dashed lines in the left plot correspond to the outlier cutoff values according to (Eq. 6), and here indeed, several points are identified as outliers (red symbols +). The model still has a problem with accommodating pH values in the range from about 6 to 7, but it fits much better for lower pH values

Robust Statistics, Fig. 2 LTS regression of pH on the composition of the major oxides. Left plot: pH versus fitted values of pH; right plot: normal QQ-plot for the LTS residuals. Red points with + are outliers

compared to the LS model. Also the QQ-plot confirms approximate normality of the (nonoutlying) residuals.

The superiority of the LTS model is also reflected in the MSE (mean-squared error), which is 0.22 (outliers not included). The MSE for the LS model is 0.61 (no outliers identified). A further interesting outcome is the inference table, which reveals the explanatory variables that are significant in the model. Accordingly, for LTS regression, the pivot coordinates for Al_2O_3 , CaO , Fe_2O_3 , K_2O , Na_2O , and LOI are significant. In contrast, for the LS model, only MnO and CaO resulted in significance, and thus the interpretation would be quite different.

In practice, there is often the desire to continue with removing the outliers, and then applying again LS regression. However, this has precisely been done with the reweighted LS step after LTS regression. Other robust regression estimators such as MM regression also determine weights for a weighted LS regression, but the weights can be in the whole interval $[0,1]$, corresponding to the outlyingness of the residuals.

Principal Component Analysis (PCA)

PCA is a dimension reduction method and widely used for data exploration. The projection onto the first two principal components (PCs) often allows to inspect the essential information contained in the data. However, in presence of outliers, classical PCs can be strongly determined by the outliers themselves, since PCs are defined as directions maximizing the (classical) variance. Usually, the PC directions are computed as the eigenvectors of the covariance matrix, which first needs to be estimated.

Covariance Estimation

Assume $(D-1)$ -dimensional observations $\mathbf{z}_1, \dots, \mathbf{z}_n$. Then the classical (empirical) covariance matrix is

$$\mathbf{S} = \frac{1}{n-1} \sum_{i=1}^n (\mathbf{z}_i - \bar{\mathbf{z}})(\mathbf{z}_i - \bar{\mathbf{z}})', \quad (7)$$

with the arithmetic mean $\bar{\mathbf{z}} = \frac{1}{n} \sum_{i=1}^n \mathbf{z}_i$. This covariance estimator is sensitive to outliers, and there are many options for a more robust estimation. One well-known estimator is the MCD (minimum covariance determinant) estimator, which is given by the mean and covariance of the subset of those h points (with $\frac{n}{2} \leq h \leq n$) which yield the smallest determinant of the empirical covariance matrix (Maronna et al. 2019). Similar to LTS regression, the choice of h determines the BP of the estimator. Higher efficiency of the estimator is achieved by a reweighting step (see Maronna et al. 2019).

PCA for the Example

Consider again the oxide composition from the GEMAS data set, which has been used above in a regression model to explain the response pH. With robust regression, several outliers in the residuals have been identified, and these are shown in the plots in Fig. 3 by red symbols +. These plots are so-called CoDa-biplots, and the compositional parts are transformed from pivot coordinates to centered logratio coefficients for a meaningful interpretation (Filzmoser et al. 2018). The left biplot is for classical PCA, based on an eigen-decomposition of the sample covariance matrix, and the right biplot for robust PCA, using the MCD estimator as a basis for the calculations.

Robust Statistics, Fig. 3 CoDa-biplots for classical (left) and robust (right) PCA of the oxide composition. Red symbols + are residual outliers from robust regression, see Fig. 2

The classical biplot reveals that the direction of the second component PC2 seems to be mainly determined by outliers, and these outliers appear in the part CaO. Note that the pivot coordinate for CaO was significant in the LS regression model, and this is very likely just an artifact of the outliers. The biplot for robust PCA is not affected by the outliers, and thus it better reflects the relationships in the oxide composition.

Summary

Robust statistical methods are supposed to give reliable results even if strict model assumptions that are required for the classical methods are violated to some extent. This means, however, that for the data majority the model assumptions need to be fulfilled. An example is multivariate outlier detection, where outlier cutoff values are usually derived from distributional assumptions valid for the data majority. There are also other approaches, in particular for outlier detection, which are not based on distributional assumptions, typically originating from the machine learning community. Methods from both disciplines can be very useful, but this also depends on the problem setting. For a recent overview in this context, see Zimek and Filzmoser (2018).

Nowadays, it is easy to compare the results of a classical and a robust statistical method, because software is freely available. For example, many robust methods are implemented in the package *robustbase* (Maechler et al. 2020) of the software environment R (R Development Core Team 2020), and the authors did their best to guarantee a similar input and output structure for the classical and robust methods. If the results of both analyses differ (clearly), one should go into detail to see why this happened.

The field of robust statistics is still very active with developing new methods and technologies. The “big data era” has not only led to bigger data sets, but also to more complex data structures, which brings in new challenges and requirements for the analysis methods. As an example, in the high-dimensional data setting it is desirable that not the complete information of an observation is discarded, but rather that only deviating entries of the observation are downweighted. For recent references to such approaches, see Filzmoser and Gregorich (2020).

Rock Fracture Pattern and Modeling

Katsuaki Koike¹ and Jin Wu²

¹Department of Urban Management, Graduate School of Engineering, Kyoto University, Kyoto, Japan

²China Railway Design Corporation, Tianjin, China

Definition

Fracture is a general term for any type of rock discontinuity (e.g., crack, fissure, joint, fault) and covers a wide size range (mm to km scale). Fractures are generated by the destruction of rock mass in a compressive or tensile stress field. Fractures are mechanically classified into the following categories: mode I, extension or opening; mode II, shear; and mode III, a mixture of modes I and II. The degree of fracture development is essential to engineering practices because it strongly affects the hydraulic and mechanical properties of rock mass including their magnitude and anisotropic behavior. Fractures are generally targeted as representative elements of a fracture pattern to characterize their development, length, orientation,

density, connectivity, aperture, and geometry (Fig. 1). Using these elements, a spatial pattern of the fracture distribution can be computationally modeled following several statistical assumptions, for which discrete fracture network (DFN) modeling is the most representative approach (e.g., Lei et al. 2017). Such computational modeling is indispensable, because the fracture distribution in rock mass is difficult to predict by 1D and 2D surveys using borehole and rock surface data, respectively. Constructed fracture models can be linked to fluid flow modeling, permeability assessments, and deformation simulations of rock mass.

Fracture Pattern Quantification Methods

Length Distribution

The true length of a fracture is impossible to measure because only a part of a fracture system appears on the rock mass surface. The trace length on the surfaces of an outcrop, tunnel, dam, or drift is therefore typically used to characterize the fracture length distribution. This distribution can be approximated using a negative power law, lognormal distribution, or negative exponential distribution (Bonnet et al. 2001). For example, the distribution of fracture length l following a negative power law with scaling exponent a and density constant α is formulated as:

$$n(l) = \alpha \cdot l^{-a} \quad (1)$$

where $n(l)dl$ is the number of fractures per unit volume in the length range $[l, l + dl]$. Because this law signifies the absence of a characteristic length, the definition of a total range

between the minimum and maximum lengths $[l_{\min}, l_{\max}]$ is necessary for practical use. Upon increasing the a value, the $n(l)$ inclination becomes steeper and the ratio of short to long fractures increases, which is demonstrated by a comparison of the simulated fracture distributions in a cubic domain of 100-m side lengths with $a = 2.5, 3.0$, and 3.5 and a length range of $[1 \text{ m}, 1000 \text{ m}]$ (Fig. 2a). Long and short fractures are dominantly distributed in models with $a = 2.5$ and 3.5 , respectively.

Orientation Distribution

Fracture orientation is defined by the strike and dip or dip and dip direction. The distribution of fracture orientation is typically approximated using a uniform, Gaussian, or Fisher distribution by considering the statistical property of the orientations, such as the dispersion and shape. Among them, the Fisher distribution (Fisher 1993), which is expressed by the following probability density distribution $f(\theta)$, has been widely adopted owing to its adequate fitness to many case studies (e.g., Hyman et al. 2016).

$$f(\theta) = \frac{\kappa \sin \theta e^{\kappa \cos \theta}}{e^{\kappa} - e^{-\kappa}} \quad (2)$$

where θ ($^\circ$) represents the deviation angle from the mean vector of the dip direction and κ is the Fisher constant that expresses the dispersion of direction clusters. Fracture orientations are scattered with small κ values and become concentrated with increasing κ values, as demonstrated by comparing two DFN models with $\kappa = 10$ and 100 in Fig. 2b. The greatest advantage of the Fisher distribution is

Rock Fracture Pattern and Modeling, Fig. 1 Representative elements for characterizing rock-fracture patterns

Rock Fracture Pattern and Modeling, Fig. 2

DFN models with different distributions of fracture length and orientation and densities in a calculation domain of $100 \times 100 \times 100$ m. (a) DFN models following a power law of length distribution with three scaling exponents a , length range [1 m, 1000 m], and $P_{32} = 0.1 \text{ m}^2/\text{m}^3$. (b) DFN models with two dispersion parameters κ with a mean dip angle of 60° and azimuth angle of 60° clockwise from the north. (c) DFN models with three fracture densities $P_{32} = 0.05, 0.1$, and $0.2 \text{ m}^2/\text{m}^3$.

the correct modeling of preferential orientation upon suitably setting the angle dispersion around the mean orientation.

Density

Fracture density is typically quantified using scale-independent indices, P_{10} , P_{21} , and P_{32} (Dershowitz and Herda 1992). $P_{10} (\text{m}^{-1})$ is the number of fractures per unit length intersected by a 1D investigation line using a scanline or borehole. $P_{21} (\text{m}/\text{m}^2)$ is the total length of fracture traces per unit surface area by 2D investigation using an outcrop or tunnel wall. $P_{32} (\text{m}^2/\text{m}^3)$ is the volumetric fracture intensity for a 3D density value expressed by the total surface area of fractures per unit volume. P_{32} is experimentally derivable from P_{10} or P_{21} because it cannot be directly measured owing to the lack of access to the interior sections of rock mass. For example, a 3D DFN model can be generated with a P_{10} value along a borehole or different P_{10} values along several boreholes by setting the fracture size and orientation distribution. The total fracture area over the calculation domain is computed, and P_{32} can therefore be quantified. More fractures are distributed and naturally connected with increasing P_{32} values, as shown in Fig. 2c.

Connectivity

The connectivity of fractures strongly affects the mechanical and hydraulic properties of rock mass. The most common method for connectivity measurements is percolation theory, which quantifies connectivity by the number of intersections per fracture using a percolation parameter p (Lei and Wang 2016). Connectivity increases with increasing p . For a 3D domain, p can be defined as the sum of $\pi^2 \times (\text{each fracture area} / \pi)^{1.5}$ per unit volume (Itasca 2019).

Aperture

The aperture is the opening width of a fracture, which is measured along the perpendicular direction of the fracture surface. The real aperture distribution is difficult to specify because natural fractures are irregularly shaped with variable apertures rather than simple plane and aperture data, which can be obtained from outcropped fractures and borehole TV observations of a rock wall. Gaussian, log-normal, negative power law, and uniform distributions have therefore been assumed for the aperture distribution (Lei et al. 2017), and one must be selected depending on the statistical properties of the measured data and rock-mass conditions.

Rock Fracture Pattern and Modeling, Fig. 3 Simulated fractures using GEOFRAC for a granitic area (modified from Koike et al. (2015)). (a) Perspective view of the locations of 2309 observed fractures from 26 deep boreholes, perspective views showing the distribution pattern of

the simulated continuous fractures viewed from (b) above, (c) the west, and (d) the lower hemisphere projection of Schmidt's net of a pole density distribution of the fractures. Each fracture is randomly and semi-transparently colored to discriminate the different fractures

The hydraulic conductivity (or permeability) of rock mass is strongly controlled by the fracture aperture because open fractures act as essential pathways of fluid flow. An open fracture is partly filled with minerals (e.g., quartz, calcite), which causes a rough fracture surface, impermeable portions in the pathway, and a highly variable aperture. The hydraulic aperture, which is substantially considered for characterizing hydraulic properties and fluid flow, is therefore considerably smaller than the aperture in general.

Geometry

Because real fracture shapes in a rock mass are impossible to specify, they must be approximated as simple regular shapes, such as planar polygons or disks (Jing and Stephansson 2007). However, complicated shapes can form by connecting several disks that are located close to one another with similar orientations and enveloping them (Koike et al. 2012).

Fractures are modeled as a smooth parallel plate for the simplest laminar fluid. For this simplification, the cubic law is

adopted in which the flow rate through the fracture is proportional to the cube of the hydraulic aperture (Witherspoon et al. 1980). For actual rock conditions, the fracture-surface roughness must be considered because roughness significantly affects the hydromechanical behavior of the fractured rock mass (Brown 1987). The joint roughness coefficient (JRC) is a representative index for the roughness measure, which can be related to the nonlinear shear strength criterion of fracture with normal stress in engineering (Barton 1976). Because JRC is known to vary with scale, self-affine or self-similar fractal models have been used for a more accurate expression of the fracture surface (e.g., Dauskardt et al. 1990; Maximo and de Lacer 2012).

Fracture Modeling

The rock fracture pattern includes the size, orientation, distribution density, aperture in some cases, and intersection, and is typically modeled using a DFN. Numerous application software programs are available for DFN modeling (e.g.,

Rock Fracture Pattern and Modeling, Fig. 4 Fracture propagation in rock mass around a tunnel with the excavation progress simulated by the hybrid FEMDEM

FLAC3D, PFC3D), as demonstrated by the example in Fig. 2 generated by FLAC3D using different geometric parameters. These applications conventionally define the probability distributions of the fracture geometric parameters and shapes as polygons or disks for modeling. These parameters are randomly selected from the probability distributions and assigned to each fracture. Geostatistical methods have also been developed for DFN modeling to honor the location and orientation data of measured fractures (e.g., Dowd et al. 2007). GEOFRAC (GEOstatistical FRACTure simulation method; Koike et al. 2015) is one such method that considers the spatial correlations of fracture orientations and densities and forms an arbitrary fracture shape by connecting several disks, as described above (Koike et al. 2012). Regional fracture patterns can be revealed using GEOFRAC from a borehole fracture dataset that show clear dominant orientations, continuous fracture distributions, and concentrated zones of parallel and intersecting fractures (Fig. 3).

Continuum- and discontinuum-based methods have been developed to model fracture initiation and propagation under tectonic stress conditions (Lisjak and Grasselli 2014; Wolper et al. 2019). The former methods are based on the mechanics of plasticity and continuum damage by assuming continuous displacement over the calculation domain, and typically use the finite element method (FEM) for the simulation. In contrast, the latter methods assume that fractures are represented by the discontinuous displacement field, and typically use the discrete element method (DEM), discontinuous deformation analysis (DDA) method, and hybrid finite-DEM (FEMDEM) for the simulation. Figure 4 shows an example of fracture propagation around a tunnel during the excavation progress, as simulated by the hybrid FEMDEM. The change in permeability and extension of the damage zone is predictable with the fracture development. Machine learning has recently been adopted to predict fracture propagation by considering the fracture geometry and mechanics (e.g., Hsu et al. 2020).

Summary

The rock fracture pattern (i.e., fracture distribution configuration) is a control factor of the hydraulic and mechanical properties of rock mass, and is typically characterized by the fracture length, orientation, density, connectivity, aperture, and geometry. The length, orientation, and aperture distributions are approximated using the most suitable statistical and power-law distributions of the fracture survey data. The volumetric fracture intensity, P_{32} (m^2/m^3), is indispensable for the 3D density to realistically model the fracture distribution in rock mass. Although this density cannot be directly measured, it is experimentally derivable from the 1D intensity P_{10} or 2D intensity P_{21} . Percolation theory is most commonly used for connectivity measurements. The fracture shape is simply approximated as a planar polygon or disk, and self-affine or self-similar fractal models are reasonable to accurately express the fracture surface.

Considering the fracture pattern, the spatial fracture distribution is typically modeled by a DFN that uses a conventional probability distribution of the geometric parameters and the fracture shape as a polygon or disk. DFN modeling is a type of nonconditional simulation. In contrast, geostatistical methods have also been developed to honor the fracture location and orientation data obtained by measurements, which includes the incorporation of spatial correlations of fracture orientations and densities into the DFN model and the formation of an arbitrary fracture shape by connecting several disks. In addition to the above static fracture modeling, dynamic fracture modeling using continuum- and discontinuum-based methods is essential for modeling fracture initiation and propagation in a tectonic stress field. Changes in the permeability and extension of the damage zone with the fracture development are predictable by dynamic modeling using a method such as hybrid FEMDEM.

Rodionov, Dmitriy Alekseevich

Hannes Thiergärtner

Department of Geosciences, Free University of Berlin, Berlin, Germany

Fig. 1 D. A. Rodionov. (Photo: Thiergärtner 1984)

Biography

Dmitriy Alekseevich Rodionov was the leading Russian scientist in applications of mathematical geosciences between 1970 and 1990 and one of the 20 founding members of the International Association for Mathematical Geology (IAMG).

Born in Saratov (Russia) on October 9, 1931, he studied geochemistry at the State University in Saratov before he started a career as exploratory geologist. Participating in a

field campaign, he befriended the mathematician Prof. Yu. V. Prochorov who inspired many young geologists about using mathematics. Rodionov obtained his PhD doctorate in the field of statistical treatment of geochemical and mineralogical data. He developed quickly into the leading expert for applied mathematical geosciences in the former Soviet Union when he worked in the Moscow Institute for Mineralogy, Geochemistry, and Crystal Chemistry of Rare Elements (IMGRE) of the Academy of Science of the USSR. On the occasion of the 23rd International Geological Congress 1968 in Prague Prof. Rodionov was one of the founding members of the IAMG and was elected as one of its Councillors. Because of the former political situation, he could not really take part in IAMG activities until 1990 but he always was in close contact with colleagues from other eastern European countries. He moved to the Moscow All-Union Institute for the Economy of Mineral Resources (VIEMS) in 1969 where he worked until 1981 as the leading specialist for the development of mathematical techniques and data processing in the field of economical geology. Under his leadership, numerous mathematical approaches were introduced for geological exploration and documented in several monographs and other publications in the Russian language. He was also one of the Russian scientists who regularly participated in the biennial scientific meetings at Příbram (then Czechoslovakia) where scientists from both political blocks could meet and exchange scientific ideas. Between 1981 and 1992, Rodionov was the director of the Laboratory for Mathematical Geology of the Institute for Ore Deposit Geology, Mineralogy, Petrology, and Geochemistry (IGEM) of the USSR Academy of Sciences in Moscow. The last few years before his demise on October 2, 1994 he worked again at VIEMS.

The IAMG honored his lifetime contributions in 1994 with the William Christian Krumbein medal.

Former friends remember Dmitriy Alekseevich as a wonderful personality. All his life he remained an agile geoscientist, always connected with the science, helpful towards colleagues and open-minded toward any new development. Last but not least, Dmitriy Alekseevich inspired everybody he worked with.

Rodriguez-Iturbe, Ignacio

B. S. Daya Sagar

Systems Science and Informatics Unit, Indian Statistical Institute, Bangalore, Karnataka, India

Fig. 1 Professor Ignacio Rodriguez-Iturbe (1942–2022) (Courtesy of Ignacio Rodriguez-Iturbe)

Biography

Ignacio Rodriguez-Iturbe is Distinguished University Professor and TEES Eminent Professor at the Departments of Ocean Engineering, Civil Engineering, and Biological and Agricultural Engineering, Texas A&M University. He is also James S. McDonnell Distinguished University Professor Emeritus at Princeton University.

Born on 8 March 1942 in Caracas, Venezuela, and educated as a civil engineer at Universidad del Zulia in Maracaibo, he finished his Ph.D. in Colorado State University (1967) under Professor Vujica Yevjevich. After teaching in Venezuela and the United States (MIT, Iowa, Texas A&M) he was in Princeton during 2000–2018 as the James

S. McDonnell Distinguished University Professor (now Emeritus) and Professor of Civil and Environmental Engineering. He is a member of numerous academies including the National Academy of Sciences, the National Academy of Engineering, the American Academy of Arts and Sciences, the Spanish Royal Society of Sciences, the Vatican Academy of Sciences, the Venezuelan National Academy of Engineering, the Mexican Academy of Engineering, the Water Academy (Sweden), the Third World Academy of Sciences, and several others.

He is the recipient of the Stockholm Water Prize (2002), the Mexico International Prize for Science and Technology (1994), the Venezuela National Science Prize (1991), the Prince Sultan Bin Abdulaziz International Water Prize (2010), the Venezuela National Engineering Research Prize (1998), the E.O. Wilson Biotechnology Pioneer Award (2009), and several other international prizes and awards. In the United States, he received from the American Geophysical Union, the Bowie Medal (2009), the Horton Medal (1998), the Macelwane Medal (1977), the Hydrologic Sciences Award (1974), and the Langbein Lecture Award (2000). He is a Fellow of the AGU and the American Meteorological Society where he received the Horton Lecture Award (1995). From the American Society of Civil Engineers he received the Huber Research Prize (1975) and the V.T.Chow Award (2001). He has Honorary Doctor's Degrees from the University of Genova (Italy, 1992), Universidad del Zulia (Venezuela, 2003), and Universidad de Cantabria (Spain, 2011) as well as Teaching Awards in the MIT Civil and Environmental Engineering Department (1974) and Universidad del Zulia (1970).

Among many other awards, he has received the Hydrology Days Award (2002) and Distinguished Alumnus Award (1994) from Colorado State University; Peter S.Eagleson Lecturer (Consortium of Universities for Hydrologic Sciences, 2010); Enrico Marchi Memorial Lecture (Italy, 2011); Chester Kiesel Memorial Lecture (Arizona, 1991); Landolt Lecture (EPFL, Switzerland, 2009); Moore Lecture (University of Virginia, 1999); Evnin Lecture (Princeton, 2000); Smallwood Distinguished Lecture (University of Florida, 2010); Distinguished Lecturer (College of Engineering, Texas A&M, 2003); Miller Research Professor (University of California, Berkeley, 2004). He is also the namesake of the "Ignacio Rodríguez-Iturbe Prize" awarded annually for the best paper in the journal "Ecohydrology."

He is the author of four books and editor of several others. His book on "Fractal River Basins: Chance and Self-Organization" coauthored with Andrea Rinaldo is a mathematically fascinating book and presents several cases supporting the self-organized nature of river basins and related terrestrial phenomena and processes (Rodríguez-Iturbe and Rinaldo 2001). He has contributed near 300 papers in international journals and many more in Proceedings and Chapters in

books. His research interests are broadly in Surface Water Hydrology with special emphasis in Ecohydrology, Hydrogeomorphology, Hydrometeorology, and the International Trade of Virtual Water.

Definition

Root mean square (RMS), also called the quadratic mean, is the square root of the mean square of a set of numbers.

Introduction

Unlike arithmetic mean which allows positive and negative numbers offset each other, RMS has a non-negative contribution from each. While RMS has many uses, such as RMS voltage in electrical engineering and RMS speed for gas molecules in statistical mechanics, in geoscience it is almost exclusively associated with root mean square error (RMSE) or root mean square deviation (RMSD).

Model simulation results, estimates with empirical formulas, and some measurements in question often need to be evaluated using more reliable measurements or theoretical predictions. Those quantities that need to be evaluated are first paired with the assumed "truth," that is, more accurate measurements or predictions. Then the pairwise differences are obtained as a set of deviation or error samples, d_i , $i = 1, \dots, n$. RMSD (or RMSE) is then defined as:

$$\text{RMSD} = \sqrt{\frac{1}{n} \sum_{i=1}^n d_i^2} \quad (1)$$

While the terms of RMSD and RMSE are interchangeable in practice, RMSE appears more frequently than RMSD in geoscience literature. Hereafter we will only use the term RMSE. Note that RMSE is scale dependent, and normalized

RMSE is sometimes employed to avoid the dependence on units.

RMSE and MAE

While RMSE is often used to measure the overall magnitude of error samples, it is often compared with mean absolute error (MAE), which is a simple arithmetic mean of the absolute values of errors. Clearly, RMSE and MAE measure the magnitude of error samples differently. The larger errors contribute to RMSE much more than the smaller errors due to the squaring operation. RMSE is suitable to describe a set of error samples that follow a normal (or Gaussian) distribution with a zero mean. If the error samples have a non-zero mean, the mean error (or the mean bias) is often removed before the standard deviation of the errors is calculated. In such a case, it is the standard error (SE) that should be used. Note that the degree of freedom is reduced by one when calculating the mean bias-corrected sample variance. In geoscience literature, unbiased RMSE is often used without correcting the degree of freedom change. However, the difference between unbiased RMSE and SE is minimal for typical large count of error samples in model evaluation studies. For error samples from a Gaussian distribution population, calculating mean and SE of the errors will allow one to reconstruct the actual distribution if there are enough samples. Table 1 shows RMSEs calculated for randomly generated pseudo-errors which follow a Gaussian distribution with a zero mean and unit standard deviation, similarly as those shown in Chai and Draxler (2014). As the sample size reaches 100 or above, using the calculated RMSEs one can reconstruct the error distribution close to its “truth” or “exact solution,” with its standard deviation within 5% to its truth (i.e., 1) as shown in Table 1. For errors following a normal distribution with non-zero mean, the error in the estimate of the mean is proportional to $1/\sqrt{n}$. With enough observations

for error samples, the error distribution can be reliably constructed using the estimated mean and SE. When there are not enough error samples, presenting the values of the errors themselves (e.g., in tables) is probably more appropriate than calculating RMSE or any other statistics.

Although sometimes error samples do not exactly follow a Gaussian distribution, the error distributions in most applications are often close to be normal distributions. It has been observed that many physical quantities that are affected by many independent processes typically follow Gaussian distributions. This phenomenon is commonly explained by the central limit theorem, which states that the properly normalized sum of independent random variables tends toward a normal distribution even if the original variables themselves are not normally distributed. There are also other explanations for the ubiquity of normal distributions (e.g., Lyon 2014). Note that the model evaluation studies where error samples are calculated as the differences between predictions and observations are focused here. Unlike some physical quantities which are often non-negative and may not directly follow a normal distribution without a mathematical transformation, the error samples in model evaluation studies usually closely resemble normal distributions.

In model evaluation studies, both the root mean square error (RMSE) and the mean absolute error (MAE) are regularly employed to measure the overall error magnitude. In the literature, RMSE is sometimes considered to be ambiguous as a metric for average model performance (e.g., Willmott and Matsuura 2005; Willmott et al. 2009). However, such suggestion is probably misleading. Chai and Draxler (2014) show that some of the arguments to avoid RMSE are indeed mistaken. For instance, RMSE actually satisfies the triangle inequality requirement for a distance metric, contrary to what was claimed by Willmott et al. (2009). Furthermore, the use of absolute value operation in calculating MAE makes the gradient or sensitivity of MAE with respect to certain model parameters difficult if not impossible. In fact, it is not wise to avoid either RMSE or MAE without considering the specifics of the application. The best statistics metric should be based on the actual distribution of the errors in order to provide a better performance measure. The MAE is suitable to describe uniformly distributed errors while RMSE is good to measure errors following a normal distribution. Also note that when both RMSE and MAE are calculated, RMSE is by definition never smaller than MAE. As any single statistical metric condenses a set of error values into a single number, it provides only one projection of samples and, therefore, emphasizes only a certain aspect of the error characteristics. Thus, a combination of metrics, including but certainly not limited to RMSE and MAE, is often required to better assess model performance. For errors sampled from an unknown distribution, providing more statistical moments of the

Root Mean Square, Table 1 RMSEs of randomly generated pseudo-errors which follow a Gaussian distribution with a zero mean and unit variance. For seven different sample sizes, $n = 4, 10, 100, 1000, 10,000, 100,000$, and $1,000,000$, five sets of errors are generated with different random seeds

n (error sample size)	RMSE				
	Set #1	Set #2	Set #3	Set #4	Set #5
4	0.9185	0.6543	1.4805	1.0253	0.7906
10	0.8047	1.1016	0.8329	0.9506	1.0099
100	1.0511	1.0293	1.0305	0.9961	1.0401
1000	1.0362	0.9772	1.0107	1.0004	1.0029
10,000	0.9974	0.9841	1.0142	0.9956	1.0023
100,000	1.0034	0.9998	1.0038	1.0028	1.0015
1,000,000	0.9996	1.0007	1.0003	0.9993	0.9996

model errors, such as mean, variance, skewness, and flatness, will help depict a better picture of the error variation.

Usage of RMSE

It is well known that RMSE is sensitive to outliers. In fact, the existence of outliers and their probability of occurrence are well described by the normal distribution underlying the use of the RMSE. Chai and Draxler (2014) showed that with a large amount of error samples that include some outliers, one can still closely reconstruct the original normal distribution. In addition, sensitivity to larger errors makes RMSE more discriminating as a model evaluation metric. This aspect is often more desirable when evaluating models. In data assimilation field, the sum of squared errors is often formed as the main component of the cost function to be minimized by adjusting model parameters. In such applications, penalizing the outliers associated with large discrepancies between model and observations through the defined least-square terms proves to be very effective in improving model performance. In practice, it might be necessary to throw out the outliers that are several orders larger than the other samples when calculating the RMSE, especially when the number of samples is limited.

Summary

Root mean square errors (RMSEs) are often used for model evaluation studies in geoscience. The arguments to choose MAE over RMSE in literature are mistaken. Compared with MAE, RMSE is suitable to measure errors which follow a normal distribution. As a more discriminating metric because of its sensitivity to large errors, RMSE is probably more desirable in model evaluations. In addition, RMS is closely related to cost function formulation in data assimilation field.

Sampling Importance: Resampling Algorithms

Anindita Dasgupta and Uttam Kumar
Spatial Computing Laboratory, Center for Data Sciences,
International Institute of Information Technology Bangalore
(IIITB), Bangalore, Karnataka, India

Definition

Sampling is a technique from which information about the entire population can be inferred. In case of remote sensing (RS) and geographic information system (GIS), training and test data are created during the early part of the project using random sampling while post-classification stratified random sampling is employed for different land-cover classes behaving as strata. RS images may have distortions that may be corrected using georectification. Georectification or georeferencing is the process of establishing mathematical relationship between the addresses of pixels in an image with the corresponding coordinates of those pixels on another image or map or ground. Georeferenced imagery is used to extract distance, polygon area, and direction information accurately. Georeferencing indicates that resampling of an image requires matching not only to a reference image but also to reference points that correspond to specific known locations on the ground. Resampling is related to but distinct from georeferencing. It is the application of interpolation to bring an image into registration with another image or a planimetrically correct map. The three methods used for resampling are nearest-neighbor, bilinear interpolation and cubic convolution. The nearest-neighbor approach uses the value of the closest input pixel for the output pixel value. Bilinear interpolation uses the weighted average of the nearest four pixels to the output pixel. Cubic convolution approach uses the weighted average of the nearest 16 pixels to the output pixel.

Introduction

Studying an entire population is both time-consuming and resource-intensive. Therefore, it is advisable to take a sample from the population of interest, and on the basis of this sample, information about the entire population is inferred. A sample is a portion, piece, or segment that is representative of a whole population. Conclusions about an entire population are drawn based on the sample information through statistical inference. A sample generally provides an accurate picture of the population from which it is drawn. It is random; each individual in the population has an equal chance of being selected (Groves et al. 2011). Different sampling schemes are explained next.

Simple random sampling: In this technique, units are independently selected one at a time until the desired sample size is achieved. Each study unit in the finite population has an equal chance of being included in the sample. This method of sampling has the advantage of representativeness, freedom from bias, and ease of sampling and analysis. The disadvantages of this method are errors in sampling, and additional time and labor requirements.

Systematic sampling: This method has evenly distributed samples over the entire population. When N units exist in the population and n units are to be selected, then sampling interval $R = N/n$. The advantage is that it is spatially well distributed with small standard errors. The disadvantages of this method are that it is less flexible to increase or decrease the sampling size and is not applicable for fragmented strata.

Stratified sampling: It involves grouping the population of interest into strata to estimate the characteristics of each stratum and improve the precision of an estimate for the entire population (Cochran 2007). Stratified random sampling is useful for data collection if the population is heterogeneous, as the entire population is divided into a number of homogeneous groups known as strata. The sampling error depends on the population variance within stratum but not between the strata (Singh and Masuku 2014). The advantage is that it

allows specifying the sample size within each stratum and different sampling design for each stratum; stratification may increase precision. The major drawbacks are that it yields large standard error if the sample size selected is not appropriate. Moreover, it is not effective if all the variables are equally important.

Cluster sampling: It involves grouping of the spatial units or objects sampled into clusters. All observations in the selected clusters are included in the sample. This method can reduce the time and expense of sampling by reducing travel distance. The disadvantage is that clustering can yield higher sampling error. Further, it can be difficult to select representative clusters.

Multistage random sampling: In this sampling, the region is separated into different subsets that are randomly selected (first stage), and then the selected subsets are randomly sampled (second stage). This is similar to stratified random sampling, except that with stratified random sampling, each stratum is sampled. However, there is stronger clustering here than simple random sampling.

Sampling in Geospatial Data Analysis

Let's understand sampling in the context of geospatial data analysis in RS applications. In case of land-cover classification from remotely sensed data, training and test reference data are randomly sampled. When the sample size is sufficient, simple random sampling provides adequate estimate of the population. While using stratified sampling, the caution is not to over-estimate the population parameter. Stratified sampling may be preferred as minimum number of samples is taken from each stratum. For example, if we consider land-cover classes such as built-up and agriculture, then samples have to be taken from both the classes. Test sample can be collected using Global Positioning System (GPS) to identify ground control points (GCPs). During early part of the project, random sampling can be employed to collect data followed by post-classification random sampling within the strata.

Sample Size

Sample size is an important part of any investigation or research project where the study seeks to make inferences about the population from a sample. When the population is heterogeneous, stratified sampling can be used and different sample sizes are collected for each population. Census method is a technique of statistical enumeration where all members of the population are studied and the sample size is equal to the population size.

Three criteria determine the appropriate sample size: level of precision, level of confidence or risk, and degree of

variability in the attributes being measured (Miaoulis and Michener 1976).

- **Level of precision:** Sampling error, also known as the level of precision, is the range in which the true value of the population is estimated (Singh, 2014). This range is expressed in percentage (e.g., $\pm 5\%$).
- **Confidence interval:** In a normal distribution, approximately 95% of the sample values are within two standard deviations of the true population value. This confidence interval is also known as the risk of error in statistical hypothesis testing.
- **Degree of variability:** When the variables exist with more homogeneous population, the sample size required is smaller. If the population is heterogeneous, larger sample size is required to obtain a given level of precision (Singh, 2014).

In case of RS data, Fitzpatrick Lins (1981) suggested that sample size N to be used to access accuracy of land-cover classified map should be determined from the formula of binomial probability theory:

$$N = \frac{Z^2(p)(q)}{E^2} \quad (1)$$

where p is the expected percent accuracy, $q = (100 - p)$, E is the allowable error, and $Z = 2$ from standard normal deviation of 1.96 from 95% two-side confidence interval. For example, if the expected accuracy is 85% and allowable error is 5%, then

$$N = \frac{2^2(85)(15)}{5^2} = 204$$

Ground Control Points (GCPs)

Remotely sensed imagery exhibits internal and external geometric error, and these random and systematic distortions are corrected by analyzing well-distributed Ground Control Points (GCPs) occurring in an image. Hence, remotely sensed data should be preprocessed to remove geometric distortion so that individual picture elements (pixels) are in their proper planimetric (x, y) map locations. GCP is a location on the surface of the Earth (e.g., a road intersection, rail-road crossings, towers, buildings, etc.) that can be identified on the remotely sensed imagery and located accurately on a map (Jenson, 1986). The locations of the output pixels are derived from locational information provided by GCPs, places on the input image that can be located with precision on the ground and on planimetrically correct maps. The locations of these points establish the geometry of the output image and its

relationship to the input image. Thus, this first step establishes the framework of pixel positions for the output image using the GCPs.

Georectification or Georeferencing

Georectification allows RS-derived information to be related to the other thematic information in GIS or spatial decision support systems (SDSS). It is the process of establishing mathematical relationship between the addresses of pixels in an image with the corresponding coordinates of those pixels on another image or map or ground. In the correction process, numerous GCPs are located in terms of their image coordinates (column and row numbers) on the distorted image and in terms of their ground coordinates. This involves fitting the coordinate system of an image to that of the second image of the same area. The transformation of remotely sensed images so that it has a scale and projections of a map is called geometric correction (Lillesand, 2015). Geometrically corrected imagery can be used to extract distance, polygon area, and direction information accurately.

In other words, rectification involves identification of geometric relationship between input pixel location (column and row) and associated map coordinates of the same point (x,y). During rectification, GCPs are selected and polynomial equations are fitted using least-squares technique. Least-squares regression is used to determine coefficients for two coordinate transformation equations that can be used to interrelate the geometrically correct (map) coordinates and the distorted image coordinates (Jenson, 1986). The correct image coordinates for any map position can be precisely estimated with the help of the coefficients from these equations:

$$x = f_1(X, Y) \quad y = f_2(X, Y)$$

where (x, y) is the correct map coordinates (column, row), (X, Y) is the distorted image coordinates, and f_1 and f_2 are the transformation functions.

GCPs should be uniformly spread across the image and present in a minimum number, depending on the type of transformation to be used. Conformal, affine, projective, and polynomial transformations are frequently used in RS image rectification. Higher-order transformation may be required such as projective and polynomial transformations to geocode an image and make it fit with another image. Depending upon the distortions in the imagery, the number of GCPs used, and their locations relative to one another, complex polynomial equations are also used. The degree of complexity of the polynomial is expressed as the order of the polynomial. The order is the highest exponent used in the polynomial.

$$x' = a_0 + a_1X + a_2Y \quad (2)$$

$$y' = b_0 + b_1X + b_2Y \quad (3)$$

where x' y' are the rectified positions (in output image), and x , y are the positions in the input distorted image.

When the six coefficients a_0 , a_1 , a_2 , b_0 , b_1 and b_2 are known, then it is possible to transfer the pixel values from the original to the rectified output image. However, before applying rectification to the entire dataset, it is important to determine how well the six coefficients derived from the least-squares regression of the initial GCPs account for the geometric distortion in the input image. The method used involves computing root mean square error (RMSE) for each of the GCPs. RMSE is the distance between the input (source or measured) location of a GCP and the retransformed (or computed) location for the same GCP (Jenson, 1986). RMS error is computed with a Euclidean distance measure, and it is a way to measure distortion for each control point.

$$\text{RMS error} = \left((x' - x_{\text{orig}})^2 + (y' - y_{\text{orig}})^2 \right)^{1/2} \quad (4)$$

where x_{orig} and y_{orig} are the original column and row coordinates of the GCP in the image, and x' and y' are the computed coordinate in the distorted image. The square root of the standard deviation represents measure of accuracy. After each computation of a transformation, the total RMSE reveals that a given set of control points exceeds the threshold. The GCP that has the highest individual error is deleted from the analysis, and the coefficients and RMSE for all the points are recomputed.

Image Resampling

It is the application of interpolation to bring an image into registration with another image or a planimetrically correct map. Resampling is related but distinct from georeferencing. Georeferencing indicates that resampling of an image requires matching not only to a reference image but also to reference points that correspond to specific known locations on the ground (Campbell and Wynne 2011).

Interpolation is applied to bring an image into registration with another image or a planimetrically correct map. Pixel brightness values (BVs) must be determined. There is no direct one-to-one relationship between the movement of input pixel values to output pixel locations. A pixel in the rectified output image often requires a value from the input pixel grid that does not fall neatly on a row-and-column coordinate. When this occurs, there must be some mechanism for determining the BV to be assigned to the output-rectified

pixel. This process is called intensity interpolation. Various popular resampling techniques used in RS applications are mentioned below.

- **Nearest-Neighbor**

The nearest-neighbor approach uses the value of the closest input pixel for the output pixel value. The pixel value occupying the closest image file coordinate to the estimated coordinate will be used for the output pixel value in the georeferenced image.

Let's try to understand this with the help of Fig. 1. The green grid is considered to be the output image to be created. To determine the value of central pixel (highlighted in light green box), in the nearest-neighbor approach, the value of the nearest original pixel is assigned, i.e., the value of black pixel in this example. In other words, the value of each output pixel is assigned on the basis of digital number closest to the pixel in the input matrix. This method has the advantage of simplicity and ability to preserve original input values as the output values. While resampling methods tend to average surrounding values, this may be an important consideration when discriminating between vegetation types or locating boundaries. This is easily computed and faster than other techniques. The disadvantage is that image has a rough appearance relative to the original unrectified data due to "stair-stepped" effect (see Fig. 2) (Bakx et al. 2012).

- **Bilinear Interpolation**

This method uses the weighted average of the nearest four pixels to the output pixel. Weighted mean is calculated for the four nearest pixels in the original image (here, it is represented as dark gray and black pixels) (see Fig. 1).

$$BV_{wt} = \frac{\sum_{k=1}^4 \frac{Z_k}{D_k^2}}{\sum_{k=1}^4 \frac{1}{D_k^2}} \quad (5)$$

where Z_k are the surrounding 4 data point values, and D_k^2 are the distances squared from the point in question (x', y') to the data points.

The advantage of this technique is that the stair-step effect caused by the nearest-neighbor approach is reduced and this image looks smooth. The disadvantage is that original data is altered and contrast is reduced by averaging neighboring values together. It is computationally more expensive than nearest-neighbor.

- **Cubic Convolution**

Cubic convolution approach uses the weighted average of the nearest 16 pixels to the output pixel. In Fig. 1, it is represented as a black and gray pixel in the input image.

Sampling Importance:

Resampling Algorithms,

Fig. 1 Principle of resampling using nearest-neighbor, bilinear interpolation, and cubic convolution. (Bakx et al. 2012)

Sampling Importance:

Resampling Algorithms,

Fig. 2 Nearest-neighbor, bilinear interpolation, and bicubic convolution. (Bakx et al. 2012)

**Sampling Importance:
Resampling Algorithms,
Fig. 3** Resampled images

The output is similar to bilinear interpolation, but the smoothing effect caused by averaging of surrounding input pixel values is more dramatic.

stepped effect is reduced and images are subsequently smoothed with bilinear and bicubic interpolation.

$$BV_{wt} = \frac{\sum_{k=1}^{16} \frac{Z_k}{D_k^2}}{\sum_{k=1}^{16} \frac{1}{D_k^2}}$$

where Z_k are the surrounding 16 data point values, and D_k^2 are the distances squared from the point in question ($x' y'$) to the data points.

The advantage is that the stair-step effect caused by the nearest-neighbor approach is reduced and the image looks much smoother (Fig. 2). The disadvantages of this method are same as that of the bilinear interpolation. It is computationally more expensive than nearest-neighbor or bilinear interpolation.

Case Study of Resampling in Remote Sensing Applications

In the following experiment, digital elevation model (DEM) of a part of Bangalore City, India, at a spatial resolution of 150 m is considered. The stair-stepped effect of nearest-neighbor is visible in Fig. 3b. It is distinctly seen within the red rectangular bonding box. Similarly, in Fig. 3c, d, the stair-

(6) Conclusions

Resampling is the application of interpolation technique to bring an image into registration with another image or a planimetrically correct map. Resampling techniques used for geo-registration are nearest-neighbor, bilinear interpolation and cubic convolution. After applying these techniques, the result obtained was observed. Nearest-neighbor was easily computed and faster than other techniques. However, the stair-stepped effect of nearest-neighbor was prominent, while the same effect reduced and images were subsequently smoothed in bilinear and bicubic interpolation approaches. However, in bilinear interpolation and cubic convolution, the original image values got altered and the contrast reduced by averaging neighboring values. These two techniques are computationally more expensive than nearest-neighbor.

Scaling and Scale Invariance

S. Lovejoy

Physics, McGill University, Montreal, Canada

Definition

Scaling is a scale symmetry that relates small and large scales of a system in scale-free, power law manner: without a characteristic scale. Because it is a symmetry, in systems with structures/fluctuations over wide ranges of scale, it is the simplest such relationship.

In one dimension, the notion of scale is usually taken as the length of an interval, and in two or higher dimensions, the Euclidean distance is often used. However, the latter is isotropic: It is restricted to “self-similar” fractals, multifractals. Most geosystems are stratified in the vertical and have other anisotropies so that the scale notion must be broadened. “Generalized Scale Invariance” does this with two elements: a definition of the unit scale (all the unit vectors) defining the scales of the nonunit vectors with an operator that changes scale by a given scale ratio. This scale-changing operator forms a group whose generator is a scale-invariant exponent.

Systems that are symmetric with respect to these scale changes may be geometric sets of points (fractals) or fields (multifractals). The relationship between scales is generally (but not necessarily) statistical and involves additional scaling relationships and corresponding scale-invariant exponents. These are often fractal dimensions, or codimensions (sets),

or corresponding dimension, codimension functions (multifractals).

Scaling Sets: Fractal Dimensions and Codimensions

Geosystems typically display structures spanning huge ranges of scale in space, in time, and in space-time. The relationship between small and large, fast and slow processes is fundamental for characterizing the dynamical regimes – for example, weather, macroweather, and climate – as well as for developing corresponding mathematical and numerical models. Since scaling can be formulated as a symmetry principle, the simplest assumption about such relationships is that they are connected in a scaling manner governed by scale-invariant exponents.

In general terms, a system is scaling if there exists a “scale free” (power law) relationship (possibly deterministic, but usually statistical) between fast and slow (time) or small and large (space, space-time). If the system is a geometric set of points – such as the set of meteorological measuring stations (Lovejoy et al. 1986) – then the set is a fractal set and the number of points n in a circle radius L varies as:

$$n(L) \propto L^D \quad (1)$$

where the (scale invariant) exponent D is the fractal dimension (Mandelbrot 1977). Consider instead, the density of points $\rho(L)$:

$$\rho(L) \propto n(L)/L^d \approx L^{-c}; \quad c = d - D \quad (2)$$

where d is the dimension of space (in this example, stations on the surface of the Earth, $d = 2$ and empirically, $D \approx 1.75$). The exponent of ρ characterizes the sparseness of the set; its exponent c is its fractal *codimension*. For geometric sets of points, it is the difference between the dimension of the embedding space and the fractal dimension of the set. More generally, codimensions characterize probabilities and therefore statistics; they are usually more useful than fractal dimensions (see below). The distinction is important for considering stochastic processes that are typically defined on infinite dimensional probability spaces so that $d, D \rightarrow \infty$ even though c remains finite. Notice that whereas $n(L)$ and $\rho(L)$ are scaling, their exponents D and c are scale invariant; the two notions are closely linked.

Scaling Functions, Fluctuations, and the Fluctuation Exponent H

Geophysically interesting systems are typically not sets of points but rather scaling fields such as the rock density or temperature $f(\underline{r}, t)$ at the space-time point $(\underline{r}, t)$. (We will generally use the term “scaling fields,” but for multifractals, the more precise notion is of singular densities of multifractal

measures). In such a system, some aspect – most often a suitably defined fluctuation – Δf – has statistics whose small and large scales are related by a scale-changing operation that involves only the scale ratios: Over the scaling range, the system has no characteristic size.

In one dimension – temporal series $f(t)$ or spatial transects, $f(x)$ – scaling can be expressed as:

$$\Delta f(\Delta t) \stackrel{d}{=} \varphi_{\Delta t} \Delta t^H \quad (3)$$

where Δf is a fluctuation, Δt is the time interval over which the fluctuation occurs, H is the fluctuation exponent, and $\varphi_{\Delta t}$ is a random variable that itself generally depends on the scale (for transects, replace Δt by the spatial interval Δx). The sign $\stackrel{d}{=}$ is in the sense of random variables; this means that the random fluctuation $\Delta f(\Delta t)$ has the same probability distribution as the random variable $\varphi_{\Delta t} \Delta t^H$. In one dimension, the notion of scale can be taken to be the absolute temporal or spatial interval Δt , Δx ; for processes in two or higher dimensional spaces, the definition of scale itself is nontrivial and we need Generalized Scale Invariance (GSI) discussed later.

Although the general framework for defining fluctuations is wavelets, the most familiar fluctuations are either $\Delta f(\Delta t)$ taken as a scale Δt difference: $\Delta f(\Delta t) = f(t) - f(t - \Delta t)$, or a scale Δt anomaly $f'_{\Delta t}$, which is the average over the interval Δt of the series $f' = f - \bar{f}$ whose overall mean $\bar{f}$ has been removed. We suppress the t dependence of Δf since we consider the case where the statistics are independent of time or space: They are respectively statistically stationary or statistically homogeneous. Physically, this is the assumption that the underlying physical processes are the same at all times and everywhere in space. Difference fluctuations are typically useful when average fluctuations increase with scale ($1 > H > 0$), whereas anomaly fluctuations are useful when they decrease with scale ($-1 < H < 0$). A simple type of fluctuation that covers both ranges (i. e., $-1 < H < 1$) is the Haar fluctuation (Lovejoy and Schertzer 2012) that appears to be adequate for almost all geoprocesses.

To see that fluctuations obey the scaling property eq. 3, consider the simplest case where φ is a random variable independent of resolution. This “simple scaling” (Lamperti 1962) is respected, for example, by regular Brownian motion in which case $H = 1/2$, $\Delta f(\Delta t)$ is a difference and φ is a Gaussian random variable. The extensions to cases $0 < H < 1$ are called “fractional Brownian motions” (fBm, Kolmogorov 1940) and to the first differences (increments) of fBm, “fractional Gaussian noises” (fGn) with $-1 < H < 0$ (Mandelbrot and Van Ness 1968). In fGn, $\Delta f(\Delta t)$ must be taken as an anomaly fluctuation $\bar{f}'_{\Delta t}$, Haar fluctuation, or other appropriate fluctuation definition.

Although Gaussian statistics are commonly assumed, in scaling processes, they are in fact exceptional. In the more usual case, at fixed scales, the “tails” (extremes) of the

probability distribution of φ is also a power law. Scaling in probability space means that for large enough thresholds s , the probability of a random φ exceeding s is $Pr(\varphi > s) \approx s^{-q_D}$. q_D is a critical exponent since statistical moments $\langle \varphi^q \rangle$ of order $q > q_D$ diverge (the notation “Pr” indicates probability, “ $\langle \rangle$ ” indicates statistical averaging, and the “ D ” subscript is because the value of the critical exponent generally depends on the dimension of space over which the process is averaged). Power law probabilities (with possibly any $q_D > 0$) are a generic property of multifractal processes; more classically, they are also a property of stable Levy variables with Levy index $0 < \alpha < 2$ (for which $q_D = \alpha$; the exceptional $\alpha = 2$ case is the Gaussian, all of whose moments converge so that $q_D = \infty$). Probability distributions with power law extremes can give rise to events that are far larger than those predicted from Gaussian models, indeed they can be so strong that they have sometimes been termed “black swans” (Adapted from Taleb 2010 who originally termed such extreme events “grey swans”). Empirical values of q_D in the range 3–7 for geofields ranging from the wind, precipitation, temperature, and seismicity have been reported in dozens of papers, (many are reviewed in ch.5 of Lovejoy and Schertzer 2013 that also includes the theory).

To see why Eq. 3 has the scaling property, consider the simplest case where the fluctuations in a temporal series $f(t)$ follow eq. 1, but with φ a random variable independent of resolution: $\varphi_{\Delta t} \stackrel{d}{=} \varphi$. If we denote $\lambda > 1$ as a scale ratio, it is easy to see that the statistics of large-scale ($\Delta f(\lambda \Delta t)$) and small-scale ($\Delta f(\Delta t)$) fluctuations are related by a power law:

$$\Delta f(\lambda \Delta t) \stackrel{d}{=} \lambda^H \Delta f(\Delta t) \quad (4)$$

Equation 4 directly shows the scaling property relating the fluctuations differing by a scale ratio λ . Since the scaling exponent H is the same at all scales, it is scale invariant.

Here and below, we treat time series and spatial sections (transects) without distinction, their scales are simply absolute differences in time Δt , or in space Δx . This ignores the sometimes important difference that – due to causality – the sign of Δt (i.e., whether the interval is forward or backward in time) can be important; whereas in space one usually assumes left-right symmetry (the sign of Δx is not important), here we treat both as absolute intervals (see Marsan et al. 1996).

Equation 4 relates the probabilities of small and large fluctuations; it is usually easier to deal with the deterministic equalities that follow by taking q^{th} order statistical moments of Eq. 3 and then averaging over a statistical ensemble (indicated by “ $\langle \rangle$ ”):

$$\langle (\Delta f(\Delta t))^q \rangle = \langle \varphi_{\Delta t}^q \rangle \Delta t^{qH} \quad (5)$$

The equality is now a usual, deterministic one. Eq. 5 is the general case where the resolution Δt is important for the

statistics of ϕ . In general, $\phi_{\Delta t}$ is a random function or field averaged at resolution Δt ; if it is scaling, its statistics will follow:

$$\langle \phi_{\lambda}^q \rangle = \lambda^{K(q)}; \quad \lambda = \tau/\Delta t \geq 1 \quad (6)$$

where τ is the “outer” (largest) scale of the scaling regime satisfied by the equation, and λ is a convenient dimensionless scale ratio. $K(q)$ is a convex ($K''(q) \geq 0$) exponent function; since the mean fluctuation is independent of scale ($\langle \phi_{\lambda} \rangle = \lambda^{K(1)} = \text{const}$), we have $K(1) = 0$.

Equation 6 describes the statistical behavior of cascade processes; these are the generic multifractal processes. Since large q moments are dominated by large, extreme values, and small q moments by common, typical values, $K(q) \neq 0$ implies a different scaling exponent for each statistical moment q : “multiscaling.” Fluctuations of various amplitudes change scale with different exponents, and each realization of the process is a multifractal: The values that exceed fixed thresholds are fractal sets. Increasing the threshold defines sparser and sparser exceedance sets (see the “spikes” in Figs. 1a and 2); the fractal dimensions of these sets decrease as the threshold is increased; this is discussed further in the next section. In general, $K(q) \neq 0$ is associated with intermittency, a topic we treat in more detail in Sect. 2.

Structure Functions and Spectra

Returning to the characterization of scaling series and transects via their fluctuations, we can combine eqs. 5, 6, to obtain:

$$S_q(\Delta t) = \langle (\Delta f(\Delta t))^q \rangle = \langle \phi_{\Delta t}^q \rangle \Delta t^{qH} \propto \Delta t^{\xi(q)};$$

$$\xi(q) = qH - K(q) \quad (7)$$

where S_q is the q^{th} order (“generalized”) structure function and $\xi(q)$ is its exponent. The structure functions are scaling since the small and large scales are related by a power law:

$$S_q(\lambda \Delta t) = \lambda^{\xi(q)} S_q(\Delta t) \quad (8)$$

When $K(q) \neq 0$, different moments change differently with scale so that, for example, the root mean square fluctuation has statistical moment $\xi(2)/2$ which can readily be smaller than the exponent of the first-order moment: $\xi(1) - \xi(2)/2 = K(2)/2 > 0$ (since $K(1) = 0$ and for all q , $K''(q) > 0$). This is shown graphically in Fig. 1a, b. A useful way of quantifying this deviation is the derivative at the mean: $C_1 = K'(1)$ where $C_1 \geq 0$ is the codimension of the mean fluctuation (see below). Typical values of C_1 are ≈ 0.05 – 0.15 for turbulent quantities (wind, temperature, humidity, and pressure (Lovejoy and Schertzer 2013) as well as topography, susceptibility, and rock density (Lovejoy and Schertzer 2007). It is significant that the Martian atmosphere has nearly identical exponents (H , C_1) to Earth (wind, temperature, and pressure, (Chen et al. 2016), and Martian topography is similarly close to Earth’s (Landais et al. 2019).

Precipitation and seismicity are notably much more extreme with $C_1 \approx 0.4$ (Lovejoy et al. 2012), ≈ 1.3 (Hooze et al. 1994). We could note that whereas the moments are “scaling,” the exponent functions such as $K(q)$, $\xi(q)$, etc. are “scale invariant.”

Scaling and Scale Invariance,

Fig. 1a A comparison of temporal and spatial macroweather series at 2° resolution. The top are the absolute first differences of a temperature time series at monthly resolution (from 80° E, 10° N, 1880–1996, annual cycle removed, displaced by 4°C for clarity), and the bottom is the series of absolute first differences (“spikes”) of a spatial latitudinal transect (annually averaged, 1990 from 60° N) as a function of longitude. One can see that while the top is noisy, it is not very “spikey”

Scaling and Scale Invariance,

Fig. 1b The first order and RMS Haar fluctuations of the series transect in Fig. 1a. One can see that in the spikey transect (space, top), the first order and RMS statistics converge at large lags (Δx), and the rate of the converge is quantified by the intermittency parameter C_1 . The time series (bottom) is less spikey, and it converges very little and has low C_1 (see Fig. 1a, top). The break in the scaling at ≈ 20 years is due to the dominance of anthropogenic effects at longer time scales. Quantitatively, the intermittency parameters near the mean are $C_1 \approx 0.12$ (space), $C_1 \approx 0.01$ (time)

Equations 7 and 8 are the statistics of (real space) fluctuations; however, it is common to analyze data with Fourier techniques. These yield the power spectrum:

$$E(\omega) \propto \langle |\tilde{f}(\omega)|^2 \rangle \quad (9)$$

where $\tilde{f}(\omega)$ is the Fourier Transform of $f(t)$, and ω is the frequency. Due to “Tauberian theorems” (e.g., Feller 1971), power laws in real space are transformed into power laws in Fourier space, hence for scaling processes:

$$E(\omega) \approx \omega^{-\beta} \quad (10)$$

where β is the spectral exponent. Due to the Wiener-Khinchin theorem, the spectrum is the Fourier transform of the autocorrelation function, itself closely related to $S_2(\Delta t)$. We therefore obtain the general relation:

$$\beta = 1 + \xi(2) = 1 + 2H - K(2) \quad (11)$$

(Technical note: Scaling is generally only followed over a finite range of scales, and unless there are cut-offs, there are generally low- or high-frequency divergences. However, if the scaling holds over wide enough ranges, then scaling in real space does imply scaling of the spectrum and vice versa, and if the scaling holds over a wide enough range, then eq. 11 relates their exponents).

Returning now to the case of simple scaling, we find $\langle \varphi^q \rangle = B_q$ where B_q is a constant independent of scale (Δt); hence we have $K(q) = 0$ and $S_q(\Delta t) \propto \Delta t^{qH}$ so that:

$$\xi(q) = qH \quad (12)$$

i.e., $\xi(q)$ is a linear function of q . This “linear scaling” with $\beta = 1 + 2H$ is also sometimes called “simple scaling.” Linear scaling arises from scaling linear transformations of noises; the general linear scaling transformation is a power law filter (multiplication of the Fourier Transform by ω^{-H}) which is equivalently a fractional integral ($H > 0$) or fractional derivative ($H < 0$). Fractional integrals of order $H + 1/2$ of Gaussian white noises yield fBm ($1 > H > 0$) and fGn ($-1 < H < 0$). The analogous Levy motions and noises are obtained by the filtering of independent Levy noises (in this case, $\xi(q)$ is only linear for $q < \alpha < 2$; for $q > \alpha$, the moments diverge so that both $\xi(q)$ and $S_q \rightarrow \infty$).

The more general “nonlinear scaling” case where $K(q)$ is nonzero is associated with fractional integrals or derivatives of order H of scaling multiplicative (not additive) random processes (cascades, multifractals). These fractional integrals ($H > 0$) or derivatives ($H < 0$) filter the Fourier Transform of φ by ω^{-H} ; this adds the extra term qH in the structure function exponent: $\xi(q) = qH - K(q)$.

In the literature, the notation “ H ” is not used consistently. It was introduced in honor of Edwin Hurst a pioneer of long memory processes sometimes called “Hurst phenomena” (Hurst 1951). Hurst introduced the rescaled range exponent notably in the study of Nile river streamflow records. To

explain Hurst's findings, Mandelbrot and Van Ness [1968] developed Gaussian scaling models (fGn, fBm) and introduced the symbol " H ." At first, this represented a "Hurst exponent," and they showed that for fGn processes, it was equal to Hurst's exponent. However, by the time of the landmark "Fractal Geometry of Nature" (Mandelbrot 1982), the usage was shifting from a scaling exponent to a model specification: the "Hurst parameter." In this new usage, the symbol H was used for both fGn and its integral fBm, even though the fBm-scaling exponent is larger by one. To avoid confusion, we will call it H_M . Subsequently, a mathematical literature has developed using H_M with $0 < H_M < 1$ to parametrize both the process (fGn) and its increments (fGn). However, also in the early 1980s (Grassberger and Procaccia 1983; Hentschel and Procaccia 1983; Schertzer and Lovejoy 1983), much more general scaling processes with an infinite hierarchy of exponents – multifractals – were discovered clearly showing that a single exponent was not enough. Schertzer and Lovejoy (1987) showed that it was nevertheless possible to keep H in the role of a mean fluctuation exponent (originally termed a cascade "conservation exponent"). This is the sense of the H exponent discussed here. As described above, using appropriate definitions of fluctuations (i.e., by the use of an appropriate wavelet), H can take on any real value. When the definition is applied to fBm, it yields the standard fBm value $H = H_M$, yet when applied to fGn, it yields $H = H_M - 1$.

Intermittency

Spikes

Often, scaling systems are modeled by linear stochastic processes, leading to linear exponent $\xi(q) = qH$, i.e., $K(q)$ is neglected; the processes are sometimes called "monofractal processes," the most common examples being fBm, fGn. Nonzero $K(q)$ is associated with the physical phenomenon of "spikiness" or *intermittency*: Compare the spatial spiky and temporal nonspiky series in Fig. 1a and their structure functions in Fig. 1b.

Classically, intermittency was first identified in laboratory flows as "spottiness" (Batchelor and Townsend 1949), in the atmosphere by the concentration of most of atmospheric fluxes in tiny, sparse (fractal) regions. In solid Earth geophysics, fields such as concentrations of ore are similarly sparse and scaling, a fact that notably prompted (de Wijs 1951) to independently develop a multiplicative (cascade) model for the distribution of ore. In the 1980s, de Wijs' model was rediscovered in statistical physics as the multifractal " p model" (see also Agterberg 2005).

Early quantitative intermittency definitions were developed originally for fields (space). These are of the "on-off" type: When the temperature, wind, or other field exceeds a threshold, then it is "on," i.e., in a special state – perhaps of

strong/violent activity. At a specific measurement resolution, the on-off intermittency can be defined as the fraction of space that the field is "on" (where it exceeds the threshold). In a scaling system, for any threshold the "on" region will be a fractal set (sparseness characterized by c , eq. 2) and threshold by exponent γ . The resulting function $c(\gamma)$ describes the intermittency over all scales and all intensities (thresholds) and is related to $K(q)$ as described below. In scaling time series, the same intermittency definition applies (note that other definitions are sometimes used in deterministic chaos).

Sometimes, the intermittency is obvious, but sometimes it is hidden and underestimated or overlooked; let us discuss some examples. In order to vividly display the nonclassical intermittency, it suffices to introduce a seemingly trivial tool – a "spike plot." A spike plot is the series (or transect) of the absolute first differences Δf normalized by their means, $\Delta f / \overline{\Delta f}$ (for a series f). Fig. 2 shows examples from the main atmospheric scaling regimes (temperatures, the middle figure corresponds to the macroweather data analyzed in Fig. 1a, 1b). Fig. 3 shows examples from solid earth geophysics. The resolutions have been chosen to be within the corresponding scaling regimes. In Fig. 2, one immediately notices that with a single exception – macroweather in time – all of the regimes are highly "spiky," exceeding the maximum expected for Gaussian processes by a large margin (the solid horizontal line). Indeed, for the five other plots, the maxima corresponds to (Gaussian) probabilities $p < 10^{-9}$ (the top dashed line), and four of the six to $p < 10^{-20}$. The exception – macroweather in time – is the only process that is close to Gaussian behavior, but even macroweather is highly non-Gaussian in space (bottom, middle). In Fig. 3, we show corresponding examples from the KTB borehole of density and susceptibility of rocks. For the susceptibility, the intermittency is so extreme as to be noticeable in the original series (upper right), but less so for the rock density (upper left). In both cases, the spike plots (bottom row) are strongly non-Gaussian with extremes corresponding to Gaussian probabilities of 10^{-15} , 10^{-162} , respectively.

Codimensions and Singularities

In order to understand the spike plots, recall that if a process is scaling, we have eq. 1 where $\varphi_{\Delta t}$ is the (normalized) flux driving the process. The normalized spikes $\Delta T / \overline{\Delta T}$ can thus be interpreted as estimates of the nondimensional, normalized driving fluxes:

$$\Delta T(\Delta t) / \overline{\Delta T(\Delta t)} = \varphi_{\Delta t, un} / \overline{\varphi_{\Delta t, un}} = \varphi_{\Delta t} \quad (13)$$

(where $\varphi_{\Delta t, un}$ is the raw, unnormalized flux, the overbar indicates an average over the series). The interpretation in terms of fluxes comes from turbulence theory and is routinely used to quantify turbulence. In the weather regime in

Scaling and Scale Invariance, Fig. 2 Temperature spike plots for weather, macroweather, climate (left to right), and time and space (top and bottom rows). The solid horizontal black line indicates the expected maximum for a Gaussian process with the same number of points (360 for each with the exception of the lower right which had only 180 points); the dashed lines are the corresponding probability levels $p = 10^{-6}$, $p = 10^{-9}$ for Gaussian processes; and two of the spikes exceed

14; $p < 10^{-77}$. The upper left is Montreal at 1 hour resolution; upper middle Montreal at 4 month resolution; upper right, paleotemperatures from Greenland ice cores (GRIP) at 240 year resolution; lower left aircraft at 280 m resolution; lower middle one monthly resolution temperatures at 1o resolution in space; lower right 140 year resolution in time, 2o in space at 45oN. Reproduced from [Lovejoy, 2018]

Scaling and Scale Invariance, Fig. 3 Density (left), magnetic susceptibility (right), nondimensionalized by their means (top), and corresponding spike plots (normalized absolute first differences, bottom). The data are from the first 2795 points of the KTB borehole, each point at a 2 m interval; the horizontal axis indicates the number of points from the surface. In the spike plots, the solid line indicates the maximum expected for a Gaussian process, the dashed lines corresponding to (Gaussian) probability levels of 10^{-9} , 10^{-12} . The extreme spikes correspond to Gaussian probabilities of $\approx 10^{-15}$, 10^{-162} , respectively

respectively time and space, the squares and cubes of the wind spikes are estimates of the turbulent energy fluxes. This spikiness is because most of the dynamically important events are sparse, hierarchically clustered, occurring mostly in storms and the center of storms.

The spikes visually display the intermittent nature of the process. As long as $H < 1$ (true for nearly all geo-processes), the differencing that yields the spikes acts as a high pass filter, and the spikes are dominated by the high frequencies. The Gaussian fGn, fBm processes – or nonscaling processes such as autoregressive and moving average processes (and the hybrid fractional versions of these) – will have spikes that look like the macroweather spikes: In Figs. 2 and 3, they will be roughly bounded by the (Gaussian) solid horizontal lines.

To go beyond Gaussians to the general multifractal scaling case, each spike is considered to be a singularity of order γ :

$$\lambda^\gamma = |\Delta f|/|\overline{\Delta f}| \quad (14)$$

λ is the scale ratio: $\lambda = (\text{the length of the series}) / (\text{the resolution of the series}) = \text{the number of pixels}$; in Fig. 3, $\lambda = 2795$. The most extreme spike ($|\Delta f|/|\overline{\Delta f}|$) therefore has a probability $\approx 1/2795$. For Gaussian processes, spikes with this probability have $|\Delta f|/|\overline{\Delta f}| = 4.47$; this is shown by the solid lines in Fig. 3; the line therefore corresponds to $\gamma = \log(|\Delta f|/|\overline{\Delta f}|) / \log \lambda \approx \log 4.47 / \log 2795 \approx 0.19$. For comparison, the actual maxima from the spike plots are $\gamma_{\max} = \log(34.5)/\log(2795) = 0.45$ and $\log(11.6)/\log(2795) = 0.30$ (susceptibility, density, respectively). These values are close to those predicted by multifractal models for these processes (for more details, see Lovejoy 2018).

To understand the spike probabilities, recall that the statistics of φ_λ were defined above by the moments, and $K(q)$. However, this is equivalent to specifying them via the corresponding (multiscaling) probability distributions:

$$\Pr(\varphi_\lambda > s) \approx \lambda^{-c(\gamma)}; \quad \gamma = \frac{\log s}{\log \lambda} \quad (15)$$

where “ $\approx$ ” indicates equality to within an unimportant prefactor and $c(\gamma)$ is the codimension function that specifies how the probabilities change with scale (Eq. 2 with $\lambda \propto L^{-1}$ and $\Pr \propto \rho$). In scaling systems, the relationship between probabilities and moments is between the corresponding scaling exponents $c(\gamma)$, $K(q)$. It turns out that it is given by the simple Legendre transformation:

$$\begin{aligned} c(\gamma) &= \max_q (q\gamma - K(q)) \\ K(q) &= \max_\gamma (q\gamma - c(\gamma)) \end{aligned} \quad (16)$$

(Parisi and Frisch 1985). The Legendre relations are generally well behaved since K and c are convex, although

discontinuities in the first- and second-order derivatives can occur notably due to the divergence of high-order moments $q > q_D$ (“multifractal phase transitions”). The Legendre transformation also allows us to interpret $c(\gamma)$ as the fractal codimension of the set of points characterized by the singular behavior λ^γ .

Returning to the spike plots, using Eq. 15 and the estimate Eq. 14 for the singularities, we can write the probability distribution of the spikes as:

$$\Pr(|\Delta f|/|\overline{\Delta f}| > s) \approx \lambda^{-c(\gamma)}; \quad \gamma = \frac{\log s}{\log \lambda} \quad (17)$$

$\Pr(|\Delta f|/|\overline{\Delta f}| > s)$ is the probability that a randomly chosen spike $|\Delta f|/|\overline{\Delta f}|$ exceeds a fixed threshold s (it is equal to one minus the more usual cumulative distribution function). $c(\gamma)$ characterizes sparseness because it quantifies how the probabilities of spikes of different amplitudes change with resolution λ (for example, when they are smoothed out by averaging). The larger $c(\gamma)$, the sparser the set of spikes that exceed the threshold $s = \lambda^\gamma$. A series is intermittent whenever it has spikes with $c > 0$. Gaussian series are not intermittent since $c(\gamma) = 0$ for all the spikes.

If there were no constraints on the system beyond scaling, an empirical specification would require the (unmanageable) determination of the entire scale-invariant functions $c(\gamma)$ or $K(q)$: the equivalent of an infinite number of parameters. Fortunately, it turns out that stable, attractive “universal” multifractal processes exist that require only two parameters:

$$K(q) = \frac{C_1}{(\alpha - 1)} (q^\alpha - q) \quad (18)$$

where $0 \leq \alpha \leq 2$ is the Levy index that characterizes the degree of multifractality (Schertzer and Lovejoy 1987). Notice that for any α , the intermittency parameter $C_1 = K'(1)$ and in addition $\alpha = K''(1)/K'(1)$. Together, α and C_1 thus characterize the tangent and curvature of K near the mean ($q = 1$). For the universal multifractal probability exponent, the Legendre transformation of eq. 18 yields:

$$c(\gamma) = C_1 \left(\frac{\gamma}{C_1 \alpha'} + \frac{1}{\alpha} \right)^{\alpha'} \quad (19)$$

where the auxiliary variable α' is defined by: $1/\alpha' + 1/\alpha = 1$. This means that processes, whose moments have exponents $K(q)$ given by eq. 7, have probabilities with exponents $c(\gamma)$ given by eq. 15. Empirically, most geofields have α in the range 1.5–1.9, not far from the “log-normal” multifractal ($\alpha = 2$).

The $c(\gamma)$, $K(q)$ codimension multifractal formalism is appropriate for stochastic multifractals (Schertzer and

Lovejoy 1987). Another commonly used multifractal formalism (often used in solid earth geophysics (Cheng and Agterberg 1996) is the dimension formalism of (Halsey et al. 1986) that was developed for characterizing phase spaces in deterministic chaos with notation $f_d(\alpha_d)$, α_d , $\tau_d(q)$. In a finite dimensional space of dimension d , $f_d(\alpha_d) = d - c(\gamma)$ where $\alpha_d = d - \gamma$, and $\tau_d(q) = (q-1)d - K(q)$ where the subscript “ d ” (the dimension of the space) has been added to emphasize that unlike c , γ , K , in the dimension formalism, the basic quantities depend on both the statistics as well as d . For example, whereas c , γ , and K are the same for 1-D transects, 2-D sections, or 3-D spaces, f_d , α_d , and τ_d are different for each subspace.

Scaling in Two or Higher Dimensional Spaces: Generalized Scale Invariance

Scale Functions and Scale-Changing Operators: From Self-Similarity to Self-Affinity

If we only consider scaling in 1-D (series and transects), the notion of scale itself can be taken simply as an interval (space, Δx) or lag (time, Δt), and large scales are simply obtained from small ones by multiplying by their scale ratio λ . More general geoscience series and transects are only 1-D subspaces of (x, t) space-time geoprocesses. In both the atmosphere and the solid earth, an obvious issue arises due to vertical/horizontal stratification: We do not expect the scaling relationship between small and large to be the same in horizontal and in vertical directions. Unsurprisingly, the corresponding transects generally have different exponents ($\xi(q)$, H , $K(q)$, $c(\gamma)$). In general, the degree of stratification of structures systematically changes with scale. To deal with this fundamental issue, we need an anisotropic definition of the notion of scale itself.

The simplest scaling stratification is called “self-affinity”: The squashing is along orthogonal directions whose directions are the same everywhere in space, for example, along the x and z axes in an x - z space, e.g., a vertical section of the atmosphere or solid earth. More generally, even horizontal sections will not be self-similar: As the scale changes, structures will be both squashed and rotated with scale. A final complication is that the anisotropy can depend not only on scale but also on position. Both cases can be dealt with by using the formalism of Generalized Scale Invariance (GSI; Schertzer and Lovejoy 1985b), corresponding respectively to linear (scale only) and nonlinear GSI (scale and position) (Lovejoy and Schertzer 2013, ch. 7; Lovejoy 2019, ch. 3).

The problem is to define the notion of scale in a system where there is no characteristic size. Often, the simplest (but usually unrealistic) “self-similar” system is simply assumed without question: The notion of scale is taken to be isotropic. In this case, it is sufficient to define the scale of a

vector $\underline{r}$ by the usual vector norm (the length of the vector $\underline{r}$ denoted by $|\underline{r}| = (x^2 + z^2)^{1/2}$. $|\underline{r}|$ satisfies the following elementary scaling rule:

$$|\lambda^{-1}\underline{r}| = \lambda^{-1}|\underline{r}| \quad (20)$$

where again, λ is a scale ratio. When $\lambda > 1$, this equation says that the scale (here, length) of the reduced, shrunken vector $\lambda^{-1}\underline{r}$ is simply reduced by the factor λ^{-1} , a statement that holds for any orientation of $\underline{r}$.

To generalize this, we introduce a more general scale function $\|\underline{r}\|$ as well as a more general scale-changing operator T_λ ; together they satisfy the analogous equation:

$$\|T_\lambda \underline{r}\| = \lambda^{-1} \|\underline{r}\| \quad (21)$$

For the system to be scaling, a reduction by scale ratio λ_1 followed by a reduction λ_2 should be equal to first reduction by λ_2 and then by λ_1 , and both should be equivalent to a single reduction by factor $\lambda = \lambda_1 \lambda_2$. The scale-changing operator therefore satisfies group properties, so T_λ is a one-parameter Lie group with generator G :

$$T_\lambda = \lambda^{-G} \quad (22)$$

When G is the identity operator (I), then $T_\lambda \underline{r} = \lambda^{-I} \underline{r} = \lambda^{-1} \underline{r}$ so that the scale reduction is the same in all directions (an isotropic reduction): $\|\lambda^{-1} \underline{r}\| = \lambda^{-1} \|\underline{r}\|$. However, a scale function that is symmetric with respect to such isotropic changes is not necessarily equal to the usual norm $|\underline{r}|$ since the vectors with unit scale (i.e., those that satisfy $\|\underline{r}\| = 1$) may be any (nonconstant, hence anisotropic) function of the polar angle – they are not necessarily circles (2D) or spheres (3D). Indeed, in order to complete the scale function definition, we must specify all the vectors whose scale is unity – the “unit ball.” If in addition to $G = I$, the unit scale is a circle (sphere), then the two conditions imply $\|\underline{r}\| = |\underline{r}|$ and we recover Eq. 20. In the more general – but still linear case where G is a linear operator (a matrix) – T_λ depends on scale but is independent of location; more generally – nonlinear GSI – G also depends on location and scale; Figs. 4, 5, 6a, 6b and 7 give some examples of scale functions, and Figs. 8a, 8b, 9 and 10 show some of the corresponding multifractal cloud, magnetization, and topography simulations.

Scaling Stratification in the Earth and Atmosphere

GSI is exploited in modeling and analyzing the earth’s density and magnetic susceptibility fields (the review Lovejoy and Schertzer 2007), and in many atmospheric fields (wind, temperature, humidity, precipitation, cloud density, and aerosol concentrations; see the monograph Lovejoy and Schertzer 2013).

Scaling and Scale Invariance, Fig. 4 A series of ellipses each separated by a factor of 1.26 in scale, red indicating the unit scale (here, a circle, thick lines). Upper left to lower right, H_z increasing from 2/5, 3/5, 4/5 (top), 1, 6/5, 7/5 (bottom, left to right). Note that when $H_z > 1$, the stratification at large scales is in the vertical rather than the horizontal direction (this is required for modeling the earth's geological strata). Reproduced from Lovejoy (2019)

Scaling and Scale Invariance, Fig. 5 Blowups and reductions by factors of 1.26 starting at circles (thick lines). The upper left shows the isotropic case, the upper right shows the self-affine (pure stratification case), the lower left example is stratified but along oblique directions, and the lower right example has structures that rotate continuously with scale while becoming increasingly stratified. The matrices used are: $\begin{pmatrix} 1.35 & 0 \\ 0 & 0.65 \end{pmatrix}$, $\begin{pmatrix} 1.35 & 0 \\ 0 & 0.65 \end{pmatrix}$, $\begin{pmatrix} 1.35 & 0.25 \\ 0.25 & 0.65 \end{pmatrix}$, and $\begin{pmatrix} 1.35 & -0.45 \\ 0.85 & 0.65 \end{pmatrix}$ (upper left to lower right). Reproduced from Lovejoy (2019)

To give the idea, we can define the “canonical” scale function for the simplest stratified system representing a vertical (x, z) section in the atmosphere or solid earth:

$$\begin{aligned} \|(x, z)\| &= l_s \left| \left(\frac{x}{l_s} \right), \text{sign}(z) \left| \frac{z}{l_s} \right| \right|^{1/H_z} \\ &= l_s \left[\left(\frac{x}{l_s} \right)^2 + \left| \frac{z}{l_s} \right|^{2/H_z} \right]^{1/2} \end{aligned} \quad (23)$$

Scaling and Scale Invariance, Fig. 6a The theoretical shapes of average vertical cross sections using the empirical parameters estimated from CloudSat – derived mean parameters: $H_z = 5/9$, with sphero-scales 1 km (top), 100 m (middle), 10 m (bottom), roughly corresponding to the geometric mean and one-standard-deviation fluctuations. In each of the three, the distance from left to right horizontally is 100 km, from top to bottom vertically is 20 km. It uses the canonical scale function. The top figure in particular shows that structures 100 km wide will be about 10 km thick whenever the sphero-scale is somewhat larger than average (Lovejoy et al. 2009)

H_z characterizes the degree of stratification (see below), and l_s is the “sphero-scale,” so-called because it defines the scale at which horizontal and vertical extents of structures are equal (although they are generally not exactly circular):

$$\|(l_s, 0)\| = \|(0, l_s)\| = l_s \quad (24)$$

It can be seen by inspection that $\|(x, z)\|$ satisfies:

$$\|T_\lambda(x, z)\| = \lambda^{-1} \|(x, z)\|; \quad T_\lambda = \lambda^{-G}; \quad G = \begin{pmatrix} 1 & 0 \\ 0 & H_z \end{pmatrix} \quad (25)$$

(note that matrix exponentiation is simple only for diagonal matrices – here $T_\lambda = \begin{pmatrix} \lambda^{-1} & 0 \\ 0 & \lambda^{-H_z} \end{pmatrix}$ – but when G is not diagonal, it can be calculated by expanding the series: $\lambda^{-G} = e^{-G \log \lambda} = 1 - G \log \lambda + (G \log \lambda)^2/2 - \dots$). Notice that in this case, the ratios of the horizontal/vertical statistical exponents (i.e., $\xi(q)$, H , $K(q)$, and $c(\gamma)$) are equal to H_z . We could also note that linear transects taken any direction other than horizontal or vertical will have two scaling regimes (with a break near the sphero-scale). However, the break is spurious; it is a consequence of using the wrong notion of scale.

Equipped with a scale function, the general anisotropic generalization of the 1-D scaling law (Eq. 1) may now be expressed by using the scale $\|\Delta r\|$:

Scaling and Scale Invariance, Fig. 6b Vertical cross-section of the magnetization scale function assuming $H_z = 2$ and a sphero-scale of 40,000 km. The scale is in kilometers and the aspect ratio is $\frac{1}{4}$ (Lovejoy et al. 2001)

Scaling and Scale Invariance, Fig. 7 The unity of geoscience illustrated via a comparison of typical (average) vertical sections in the atmosphere (top), and in the solid earth (bottom), an aspect ratio of 1/5 was used. The key points are as follows: $H_z < 1$, l_s small (atmosphere, stratification increasing at larger scales) and $H_z > 1$, l_s large (solid earth, stratification increasing at smaller scales). The sphero-scale (l_s) varies in space and in time (see Fig. 6a, 6b)

$$\Delta f(\Delta r) \stackrel{d}{=} \varphi_{\|\Delta r\|} \|\Delta r\|^H \quad (26)$$

This shows that the full scaling model or full characterization of scaling requires the specification of the notion of scale via the scale-invariant generator G and unit ball (hence the scale function), the fluctuation exponent H , as well the statistics of $\varphi_{\|\Delta r\|}$ specified via $K(q)$, $c(\gamma)$ or – for universal multifractals, C_1 , α . In many practical cases – e.g., vertical stratification – the direction of the anisotropy is fairly obvious, but in horizontal sections, where there can easily be significant rotation of structures with scale, the empirical determination of G and the scale function is a difficult, generally unsolved problem.

In the atmosphere, it appears that the dynamics are dominated by Kolmogorov scaling in the horizontal ($H_h = 1/3$) and Bolgiano-Obukhov scaling in the vertical ($H_v = 3/5$) so that $H_z = H_h/H_v = 5/9 = 0.555\dots$ Assuming that the horizontal directions have the same scaling, then typical structures of size $L \times L$ in the horizontal have vertical extents of L^{H_z} , hence their volumes are $L^{D_{el}}$ with “elliptical dimension” $D_{el} = 2 + H_z = 2.555\dots$; the “23/9D model” (Schertzer and Lovejoy 1985a). This model is very close to the empirical data, and it contradicts the “standard model” that is based on isotropic symmetries and that attempts to combine a small-

scale isotropic 3D regime and a large-scale isotropic (flat) 2D regime with a transition supposedly near the atmospheric scale height of 10 km. The requisite transition has never been observed, and claims of large-scale 2D “geostrophic” turbulence have been shown to be spurious (reviewed in ch. 2 of Lovejoy and Schertzer 2013).

Since $H_z < 1$, the atmosphere becomes increasingly stratified at large scales. In solid earth applications, it was found that $H_z \approx 2-3$ (rock density, susceptibility, and hydraulic conductivity (Lovejoy and Schertzer 2007)) i.e., $H_z > 1$ implying on the contrary that the earth’s strata are typically more horizontally stratified at the smallest scales (Figs. 6a, 6b and 7).

Conclusions

Geosystems typically involve structures spanning wide ranges of scale: from the size of the planet down to millimetric dissipations scales (the atmosphere) or micrometric scales (solid earth). Classical approaches stem from the outdated belief that complex behavior requires complicated models. The result is a complicated “scalebound” paradigm involving hierarchies of phenomenological models / mechanisms each spanning small ranges of scale. For example, conventionally, the atmosphere was already divided into synoptic, meso- and microscales when Orlanski (1975) proposed further divisions implying new mechanisms every factor of two or so in scale. Ironically, this still popular paradigm arose at the same time that scale-free numerical weather and climate models were being developed that were based on the scaling dynamical equations and now known to display scaling meteorological fields.

At the same time as the scale-bound paradigm was ossifying, the “Fractal Geometry of Nature” (Mandelbrot 1977, 1982) proposed an opposite approach based on sets that respected an isotropic scaling symmetry: self-similar fractals. These have scale-free power law number-size relationships whose exponents are scale-invariant geo-applications already included topography and clouds. However, geosystems are rarely geometric sets of points but rather fields (i.e., with values, e.g., temperature, rock density) varying in space and

Scaling and Scale Invariance, Fig. 8a Simulations of the liquid water density field. The top is a horizontal section, to the right the corresponding central horizontal cross section of the scale function. The stratification is determined by $H_z = 0.555$ with $l_s = 32$. The bottom

shows side views. There is also horizontal anisotropy with rotation. Statistical (multifractal) parameters: $\alpha = 1.8$, $C_1 = 0.1$, and $H = 0.333$, on a $512 \times 512 \times 64$ grid (Lovejoy and Schertzer 2013)

Scaling and Scale Invariance, Fig. 8b The top is the visible radiation field (corresponding to Fig. 8a), looking up (sun at 45° from the right); the bottom is a side radiation field (one of the 512×64 pixel sides) (Lovejoy and Schertzer 2013)

Scaling and Scale Invariance, Fig. 9 Numerical simulation of a multifractal rock magnetization field (vertical, component M_z) with parameters deduced from rock samples and near surface magnetic anomalies (Pecknold et al. 2001). The simulation was horizontally isotropic with vertical stratification specified by $H_z = 1.7$, $l_s = 2500$ km; the region is $32 \times 32 \times 16$ km, resolution 0.25 km. The statistical parameters specifying the horizontal multifractal statistics are $H = 0.2$, $\alpha = 1.98$, and $C_1 = 0.08$. This is a reasonably realistic crustal section, although the spheroscale was taken to be a bit too small in order that strata may be easily visible. Notice that the structures become more stratified at smaller scales. The direction of M is assumed to be fixed in the z direction

Scaling and Scale Invariance, Fig. 10 Comparison of isotropic versus anisotropic simulations for three different scaling models. Top row shows the scale functions. From left to right, we change the type of anisotropy: The left column is self-similar (isotropic) while the middle and right columns are anisotropic and symmetric with respect to $G = \begin{pmatrix} 0.8 & -0.5 \\ 0.05 & 1.2 \end{pmatrix}$. The middle column has unit ball circular at 1 pixel, while for the right one the unit ball is also anisotropic. The second, third, and fourth rows show the corresponding fBm (with $H = 0.7$), the analogous fractional Levy motion (fLm $\alpha = 1.8$, $H = 0.7$), and multifractal ($\alpha = 1.8$, $C1 = 0.12$, $H = 0.7$) simulations. We note that in the case of fBm, one mainly

perceives textures; there are no very extreme mountains or other morphologies evident. One can see that the fLm is too extreme; the shape of the singularity (particularly visible in the far right) is quite visible in the highest mountain shapes. The multifractal simulations are more realistic in that there is a more subtle hierarchy of mountains. When the contour lines of the scale functions are close, the scale $\|x\|$ changes rapidly over short distances. For a given order of singularity γ , λ^γ will therefore be larger. This explains the strong variability depending on direction (middle bottom row) and on shape of unit ball (right bottom row). Indeed, spectral exponents will be different along the different eigenvectors of G (Lovejoy and Schertzer 2007).

in time. In addition, these fields are typically highly anisotropic notably with highly stratified vertical sections. In the 1980s, the necessary generalizations to scaling fields (multifractals) and to anisotropic scaling (Generalized Scale Invariance, GSI) were achieved.

GSI clarifies the significance of scaling in geoscience since it shows that scaling is a rather general symmetry principle: It is thus the simplest relation between scales. Just as the classical symmetries (temporal, spatial invariance, and directional invariance) are equivalent (Noether's theorem) to conservation laws (energy, momentum, and angular momentum), the

(nonclassical) scaling symmetry conserves the scaling functions G , K , and c . Symmetries are fundamental since they embody the simplest possible assumption, model: Under a system change, there is an invariant. In physics, initial assumptions about a system are that it respects symmetries. Symmetry breaking is only introduced on the basis of strong evidence or theoretical justification: in the case of scale symmetries, they are broken by the introduction of characteristic space or time scales.

Theoretically, scaling is a unifying geophysical principle that has already shown its realism in numerous geoapplications both on Earth and Mars proving the pertinence of anisotropic scaling models and analyses. It is unfortunate that in geoscience, scale-bound models and analyses continue to be justified on superficial phenomenological grounds. Geoapplications of scaling are therefore still in their infancy.

Scattergram

Richard J. Howarth
Department of Earth Sciences, University College London
(UCL), London, UK

Synonyms

Crossplot; Dotplot; Pointplot; Scattergraph; Scatterplot; xy-plot

Definition

Scattergram is a contraction of *scatter diagram*, a term which also occurs in the literature. It is a bivariate graph in which pairs of values of two variates (x , y) are plotted as points, using coordinates based on their numerical values on two orthogonal axes in which the x -axis is conventionally horizontal and the y -axis vertical. If one variate is known to be dependent in some way on the other, the y -axis is assigned to the dependent variate. The axes are scaled with regard to a continuous range of the possible, or observed, values of a variate, and each may use either arithmetic or logarithmic scaling. Figure 1 is an early example from the geological literature.

The synonyms *crossplot*, *dotplot*, *pointplot*, *scattergraph*, and *scatterplot* are sometimes written as two separate words which may, or may not, be hyphenated, but such forms are much less frequent; *xy-plot* is also occasionally used. Since the 1990s, *scatterplot* has become established as the most frequently used term (e.g., in Reimann et al. (2008), which, despite its general title, deals largely with regional geochemical data). The terms *scattergram*, *scatter plot*, and *scattergraph* were all in use by the early 1920s, *crossplot* was in use by 1940, and *dotplot* was introduced in the 1960s. Apart from “*xy-plot*,” hyphenation is uncommon today.

Data on the annual frequency of usage of these terms were retrieved, ignoring case, from the Google Books 2012 English corpus, which comprises all the words extracted by optical character recognition from the scanned text of some eight million “books” (which include bound journal volumes) using the *ngramr* package of Carmody (2015). Words occurring less than 40 times in the corpus are not recorded in the publicly available database (Michel et al. 2011), so in some

cases it may be impossible to find when the actual “first” use of a given word took place.

The raw frequency counts for each term were normalized relative to the average annual frequency of occurrence of a set of “neutral” English “words with little or no specific meaning,” *the, of, and, in, a, is, was, not, and other*, and are shown in Fig. 2 as the number of occurrences per million words, as advocated by Younes and Reips (2019). The time trends were obtained by smoothing, using robust locally weighted regression with a 7-year moving window. On account of the large variation in the frequency of usage of different terms, the time trends are shown as a semilogarithmic chart, in which an exponential increase in usage with time becomes linear (the term *scatterplot* exhibits this type of behavior).

Early examples of usage in the Earth sciences include *scatter diagram* by Krumbein and Pettijohn (1938), *scattergram* by Burma (1948), and *scatterplot* by Mason and Folk (1958). Plots in which the x -axis corresponds to time or to an ordered list of abbreviations for chemical element names, etc., are usually referred to by other titles (such as a time-series plot, spider plot, and so on). Scattergrams have long been used in igneous and sedimentary petrology to show compositional trends or to assign samples to a class using one of many existing classification schemes (e.g., the $(\text{Na}_2\text{O} + \text{K}_2\text{O})$ vs. SiO_2 “total alkali silica” or “TAS diagram,” for volcanic and plutonic rocks of Cox et al. (1979); see also Janoušek et al. (2016)), for plotting isotopic ratios (e.g., $^{87}\text{Sr}/^{86}\text{Sr}$ vs. $^{206}\text{Pb}/^{204}\text{Pb}$), and so on.

In some cases, the values of an associated categorical attribute, such as geographical location or class affinity, or the value of a third continuous variate, may be shown by means of discrete symbols of different shapes, proportional symbol sizes, or colored symbols of the same or different shapes. If there is too large a number of datapoints of the same type to distinguish them individually, then the value of a third

Scattergram,

variate may be shown using isolines. Spatial point density within a plot may be shown in a similar way.

Correlation between the x - and y -variates in a scattergram is visually assessed by the closeness of fit of the datapoints to a line, or curve. If a formal fit by a function is required, then it should be accomplished using an appropriate linear or non-linear regression algorithm. In doing so, it should be noted whether measurement errors (or similar) are associated with x , y , or both, and an appropriate regression method applied. It should also be borne in mind that correlation is inherent in the so-called “closed” percentaged and other constant-sum data. Specialized techniques for dealing with such “compositional data” exist (e.g., Buccianti et al. 2006; Tsagris et al. 2020).

Authors, referees, and editors should all bear in mind that because of the expense of color-printed figures in journals (often charged to the author), some illustrations may appear in the printed, as opposed to online, version of an article using monochrome tones of gray. Care should therefore be taken to ensure that the essential information to be conveyed by an illustration, which may appear evident enough when viewed in color on a computer screen or in a color print, can also be distinguished in a monochrome version. Some “temperature” color scales used to depict the value of a third variate often use pastel colors which can be difficult to distinguish individually. A check should also be made for use of colors which those who are color-blind cannot distinguish (e.g., using <https://www.color-blindness.com/coblis-color-blindness-simulator/>). Ensuring clear distinction may require submission of two differently drawn versions of the same illustration for publication.

Scatterplots may also be used as visual goodness-of-fit tests when the observed frequency distribution for a set of data is fitted by a theoretical model, e.g., in quantile-quantile plots, percentile-percentile plots, cumulative probability

plots, and also to find possible outliers using chi-square plots (see Reimann et al. 2008 for discussion).

Summary

A scattergram has long been one of the most commonly used graphical displays in the geological literature, providing a useful visual synopsis of the relationship between two (or three) variates which the eye can easily assimilate. However, some thought is required to ensure that its design is such that its message can be most effectively conveyed in all circumstances.

Schuenemeyer, John H.

Donald Gautier

DonGautier L.L.C., Palo Alto, CA, USA

Fig. 1 Jack Schuenemeyer (Courtesy of J. Schuenemeyer)

Biography

John H. (Jack) Schuenemeyer is an American mathematical statistician known for his work in mass balance stochastic analysis, discovery process modeling, probabilistic resource assessment, uncertainty evaluation, and statistical education. He is emeritus professor of mathematical sciences at the University of Delaware, an elected member of the International Statistics Institute, Fellow of the American Statistical Association, Distinguished Lecturer for the International Association of Mathematical Geosciences, and recipient of the John Cedric Griffiths Award for excellence in teaching mathematical geology.

Schuenemeyer was born in St. Louis, Missouri, on October 19, 1938, to descendants of German immigrants. He grew up in the St. Louis area with a love of baseball and mathematics. Two years at Washington University showed that an engineering career was not for him, so he joined the US Air Force. While stationed at Lowry Air Force Base, near Denver, Colorado, he met his future wife, Judy, with whom he would ultimately have three children.

Upon return to civilian life, he was hired by RCA in New Jersey as a computer programmer. He then returned to Denver where he worked for the US Bureau of Mines and enrolled in the University of Colorado, earning B.S. and M.S. degrees in Applied Mathematics. In 1972, he was accepted to the University of Georgia, where Prof. Ralph Bargmann supervised his doctoral work in multivariate statistics; he received his Ph. D. in 1975.

The following year, Dr. Schuenemeyer joined the University of Delaware faculty, initially as an assistant professor and then as full professor of mathematics with joint appointments in Geology and Geography. At Delaware, he taught graduate and undergraduate courses in statistics and supervised numerous graduate students, while simultaneously conducting research in applied statistics. An important part of his research was a fruitful collaboration with the US Geological Survey, for whom he developed quantitative techniques for resource evaluation and provided methodological leadership in spatial analysis, nonparametric regression analysis, discovery process modeling, and dependency evaluation. In 1998, he retired from the university to work full time at the USGS as a research statistician, before moving to Cortez, Colorado, to found Southwest Statistical Consulting L.L.C.

Schuenemeyer is a devoted advocate of high-quality education for all members of society, including the financially disadvantaged. For many years, he has volunteered his expertise as a member and president of his local school board in Cortez where he lives with his wife, Judy, a retired attorney.

Schwarzacher, Walther

Jennifer McKinley

Geography, School of Natural and Built Environment,
Queen's University, Belfast, UK

Fig.1 Professor Walther Schwarzacher. (Taken by Jennifer McKinley, 23 April, 2015)

Biography

Professor Walther Schwarzacher was born in 1925 in Graz, Austria. He completed both his undergraduate studies and his doctoral dissertation in a total of 4 years at Innsbruck University, Austria, under the supervision of the distinguished geologist Bruno Sander. Walther was awarded a British Council Scholarship to Cambridge University, where he became a member of the University Natural Science Club and participated in an expedition to Spitsbergen. In recognition of Walther's respect for his academic supervisor, Bruno Sander, he was proud to name a glacier in Spitsbergen after him. Walther made many lifelong friends during his professional life. His advisor at Cambridge, Percival Allen, suggested that he should consider an open position in the Geology Department of Queen's University Belfast, UK. Walther joined Queen's University Belfast as an assistant lecturer in 1949. He was promoted to lecturer, reader, and eventually professor when he was appointed to a personal chair in mathematical geosciences in 1977. In 1967/1968, Walther was distinguished visiting lecturer in the newly formed mathematical geology section at the Geological Survey of Kansas. During this year, he applied statistical time series analysis to local Pennsylvanian limestone-shale sequences and performed experiments simulating the Kansas cyclothems. Walther also spent sabbaticals at the Christian Albrechts University Kiel.

His former head of the school at Queen's University Belfast, Professor Julian Orford, recounts "Walther had a strong belief that geology had a story that could be explained by maths – in particular cycles and rhythms in sediment deposition and planetary motions that such cycles might be associated with." After 65 years including 25 years as emeritus professor, Walther retired but continued to inspire many through his pioneering research on Markov processes. Walther was one of the first researchers to find evidence for Milankovitch cycles, periodic variations in the Earth's orbit, and in the thickness of sedimentary facies. He wrote two influential books in the field of sedimentology and many international publications and chapters. The first book *Sedimentation Models and Quantitative Stratigraphy* (dedicated to A.B. Vistelius and W.C. Krumbein) was published by Elsevier in 1975. In it he proposed stochastic models for sedimentary processes introducing applications of Markov chains and the use of semi-Markov processes. The second book *Cyclostratigraphy and the Milankovitch Theory* which was published in 1993 contains his original evidence for Milankovitch cycles in the thicknesses of coupled limestone and marl beds.

Professor Walther Schwarzacher was a founding member of the International Association for Mathematical Geosciences (IAMG). From 1980 to 1986, Walther was a lecturer in the "Flying Circus" offering short courses in nine countries on four continents under the auspices of the Quantitative Stratigraphy Project of the UNESCO-sponsored International Geological Correlation Program. This included field trips in Brazil, India, and China, accompanied by his wife June. He was extremely proud to have published in the first ever edition of *Mathematical Geology* (now *Mathematical Geosciences*) the first and flagship journal of the Association. The IAMG recognized his scientific contributions through the award in 1977 of the William Christian Krumbein Medal, the second Krumbein Medal to be awarded. This is the highest award given by the Association in recognition of outstanding career achievement and distinction in the application of mathematics or informatics in the Earth sciences, service to the IAMG, and support to professions involved in the Earth sciences. This fully reflects Walther's dedication to advancing mathematical geoscience in quantitative sedimentology and stratigraphy.

I knew Walther for many years, as one of my lecturers in the former Geology Department at Queen's University Belfast and later as a colleague in Queen's and the IAMG. I was pleased that his role in establishing mathematical geoscience and as a founding member of the IAMG was acknowledged through recognition as an honorary IAMG member. Walther's research continues to inspire researchers to use a quantitative cyclo-stratigraphic approach.

Acknowledgments I would like to thank Walther's wife, June, family, and friends for the information and inspirational stories for this biography.

Sedimentation: Deposition, Accumulation.

Diagenesis: Lithification.

Definition

Sedimentation and diagenesis are the act and process of forming sedimentary rocks distributed on the surface of Earth's crust. During sedimentation, fluid sediment composed of particles flows, deposits, and accumulates with varying degrees of sorting. The accumulating sediments forms layers and becomes buried. After sedimentation, the process gradually progresses to diagenesis. Conditions such as temperature, pressure, and the chemical environment change with burial, in which sediment changes into solid rock.

Sedimentation is a phenomenon that occurs on the surface of Earth's crust, in which terrigenous clastic sediments, which are particle grains from rocks formed by weathering and/or erosion sink, accumulate and pile onto the surface and/or bottoms of water bodies by fluid motion. The origin of sedimentary particles can be divided into two types: clastic and biogenic. Gravel, sand, and mud are particles derived from sedimentary, igneous, and metamorphic rocks. Biogenic sediment includes skeletal remains of mollusks, echinoderms, foraminifera, diatoms, coral, etc.

Diagenesis is a gradual process that constitutes the first stage of burial after sedimentation. Variations in temperature and pressure with burial change the physical and chemical properties of the sediment. Dehydration, by increasing the overburden pressure, and the dissolution of minerals caused by an increase in the contact surface, leads to decreased porosity and increased density, which is the process of lithification.

Introduction

On the surface of the solid Earth, particles of the crust are mobile. Crustal surface features, such as mountains, are decomposed physically and chemically by weathering. The eroded particles are transported to the ocean and/or lake by fluids, wind, glaciers, and tides. Transported particles deposit at the bottom of the water and/or on the surface of the ground. This deposition process is called sedimentation. The sediments change their properties during burial. As the sediments are buried deeper, the sedimentary rocks notably change. On the surface of Earth's crust, weathering, erosion, transportation, deposition, burying, and metamorphism occur in that order. In this process, deposition and lithification during burial are “sedimentation” and “diagenesis,” respectively. These two processes are complicated and interact with each other. Because sedimentation and diagenesis are related to the generation of natural disasters and natural resources, these phenomena are also relevant to human society. Therefore, understanding the processes of sedimentation and diagenesis is important.

Sedimentation Processes and Sedimentary Structures

When a particle becomes gravitationally unstable due to the flow of air and/or water, the particle begins to move. When the flow speed decreases or the particle reaches a gravitationally stable position, the particles stop and deposit. Terrigenous clastic sediment generated in mountainous areas are transported along rivers and are deposited in lakes and the ocean. Lakes and the ocean are stable (low potential) environments for transported sediment particles. Large-grained gravels are deposited in estuaries and coasts with strong currents. On the other hand, fine silt and clay particles are carried offshore and deposited where the flow is calm.

The settling velocity of sedimentary particles depends on the density of the fluid and the particle size. In the case of quartz with a perfect spherical shape, when the particle Reynolds number is less than 1 ($Re < 1$), the settling velocity depends on Stokes law:

$$v = \frac{(\sigma - \rho)g}{18\eta} d^2$$

where d , σ , ρ , η , and g are the radius of the particle, density of the particle, density of the fluid, viscosity coefficient, and gravitational acceleration, respectively. On the other hand, when the Reynolds number for the particle is more than 1 ($R_e > 1$), the settling velocity depends on the impact law (Newton's law):

$$v^2 = \frac{4(\sigma - \rho)g}{3C_D\rho} d$$

where C_D is drag coefficient. Figure 1 shows the relationship between the radius of the sphere and the settling velocity of quartz with a perfect spherical shape. The settling velocity of quartz particles whose radius is less than 100 μm mostly follow Stokes law, which is less than 1.0 cm/s. Large particles of quartz with radii greater than 2000 μm have settling velocities closer to the impact law, although there can be some differences.

Sedimentation and Diagenesis, Fig. 1 Settling velocity versus sphere diameter of quartz particles. (After Gibbs et al. 1971)

Sedimentary conditions such as the sedimentation rate, particle size, fluid density, etc. are recorded in sedimentary rocks as sedimentary structures (Fig. 2). Figure 2a shows the gradual distribution of particles. Large particles are distributed at the bottom and small particles are distributed at the top, which is called graded bedding. Graded bedding shows that the sorting of the particles depends on density differences. Figure 2b depicts a flame structure. When heavier sediments are layered on top of unconsolidated sediments immediately after deposition, the upper sediments sink due to their weight, creating a sedimentary structure in which the lower sediments flow upwards. In Fig. 2b, the white layer is composed of pumice, and the black layer includes scoria. The densities of pumice and scoria are generally $\sim 1.0 \text{ g/cm}^3$ and $\sim 2.0 \text{ g/cm}^3$, respectively. After the sedimentation of pumice, scoria was deposited on the pumice layer. At that time, a part of the pumice layer rose up to the surface because there was a density difference at the boundary of the two layers.

When particles are deposited via fluid currents, winds and waves, the surface of sediment is called a bedform and is related to the condition of the sediments. When the current speed increases at the same depth, a bedform composed of medium sand changes from flat, to ripple, dune, transition, plane bed, standing wave, and antidune. Evidence of the current is recorded in the sediments and/or rocks as a sediment structure called a lamination. Figure 2c shows a stripe pattern indicative of lamination. This pattern would typically have formed in a slow fluid flow and indicates that the sedimentary surface had previously been rippled.

Human Society and Sedimentation

Turbidity currents are one type of sedimentary gravity flows. Particles of sand and mud from land enter seawater, form high-density current flows, and are deposited. These current flows erode the seafloor surface. Terrestrial sediment includes organic matter such as plants and organisms, which become natural resources; therefore, turbidites play an important role in transporting organic sediments to the seafloor. On the other hand, turbidites can be generated by earthquakes (seismoturbidites) and tsunami deposits and are thus important in the study of disasters. Because seismoturbidites are evidence of past earthquake occurrences, recurrence intervals of earthquakes can be estimated by analyzing the distribution of seismoturbidites (cf. Adams 1990). Tsunami deposits are important records of large earthquakes in the past. Recently, new technology has been used in the field of sedimentology to understand the complex condition and structure of sedimentary flows. Mitra et al. (2021) reconstructed the flow conditions of tsunami deposits using a deep neural network inverse model and obtained a simulation result that was consistent with the observed values of the flow conditions, such as the

Sedimentation and Diagenesis, Fig. 2 Sedimentary structures in rocks. (a) Graded bedding. Large particles are distributed at the bottom and small particles are distributed at the top. (b) Flame structure. The white layer is composed of pumice, and the black layer includes scoria.

maximum inundation distance, flow velocity, and maximum flow depth. Their results indicate that the deep neural network inverse model has the potential to estimate the physical characteristics of modern tsunamis.

Diagenesis

As sediment is buried deep underground, the temperature and pressure rise; therefore, its physical and chemical properties change continuously over time. In the process of diagenesis, the following phenomena occur as the process generates rock from sediments.

- **Consolidation:** The porosity of the sediments decreases, and the density increases. The consolidation typically progresses with dehydration.
- **Cementation:** The constituent particles become bound to each other, and the pore space is filled by minerals. Representative filled minerals are carbonate and silicate minerals.
- **Replacement:** Primary minerals are replaced by secondary minerals. Calcareous sediment replaces dolomite during diagenesis (dolomitization).
- **Differential solution:** Differential solutions are caused by differences in constituent minerals. The phenomenon in which one of them dissolves discriminatively due to the pressure by the contact part of minerals and/or gravel is called the pressure solution.
- **Recrystallization:** The existing minerals grow crystals.
- **Authigenesis:** This process is a self-sustaining action of new minerals. The generation of authigenic minerals relates to the temperature and chemical state in diagenesis.

A part of the pumice layer rose up to the surface because there was a density difference at the boundary of the two layers. (c) Lamination. A stripe pattern would typically have formed in a slow fluid flow and indicates that the sedimentary surface had previously been rippled

Representative authigenic minerals are clay minerals such as kaolinite, smectite, montmorillonite, and illite.

- **Organic maturation:** Organic matter included in the sediments changes properties with increasing temperature and pressure due to burial.

Consolidation, cementation, recrystallization, replacement, differential solution, and authigenesis make sediments harder and transform sediments into rock (lithification). On the other hand, organic maturation is the reaction of organic matter included in the sediment, which is involved in the generation process of natural resources such as natural gas and oil. The generation of natural resources from organic matter is controlled by the environment conditions, especially temperature, and pressure.

Interaction of Sedimentation and Diagenesis

Generally, diagenesis is a process that occurs after sedimentation. However, there is a reverse situation in which diagenesis generates sediments. For example, consolidation, which is one of the diagenetic processes, decreases the pore volume due to a decrease in porosity with dehydration. The progress of consolidation is governed by the difference between the overburden pressure and the pore pressure. Immediately after deposition, the permeability is high because it is in an unconsolidated state. Therefore, dehydration easily occurs and consolidation progresses. However, in the case of low permeability, for instance, due to a high sedimentation rate, pore water cannot escape to the surface, and the pore pressure increases, in which consolidation is decelerated. The generated high pore pressure reduces the stability of the ground. As a result, the seafloor collapses, which forms mass transport

depositions (MTDs). In fact, MTDs distributed in the high pore pressure zone are confirmed. Kamiya et al. (2018) calculated the level of consolidation of formations including MTDs in the Boso Peninsula, Central Japan. As a result, the consolidation level (consolidation yield stress) of the layers including MTDs is less than that of other formations, which indicates that the high pore pressure prevented consolidation and generated mass transport. Thus, sedimentation and diagenesis can interact. The surface layer of the solid Earth is undergoing complex and diverse dynamic actions.

Summary

During sedimentation, different sedimentary structures are created depending on what, where, and how sediments are deposited. After deposition, the alteration process of minerals and organic matter differs depending on the environment in which they are buried. Through such a process of deposition and diagenesis, the complex surface material of the Earth is produced. In addition to research that explores past environments through observational analyses, numerical analyses based on probability theory are also being conducted. From the perspective of disaster prevention and the production of natural resources such as minerals and petroleum, research on Earth's surface will continue to be important.

Definition of the Biological and Formal Neurons

In the brain, neurons are linked together through axons and dendrites; Fig. 1 is a synthetic presentation of the human neuron. As a first approach, we can consider that these links are conductors and can thus convey messages from one neuron to another. The dendrites are the inputs of a neuron and its axon are the outputs (Mejia 1992).

A neuron emits an electrical signal based on coming signals from other neurons. We observe, in fact, at the level of a neuron, a summation of signals received over time and the neuron in turn emits an electrical signal when the sum exceeds certain threshold.

A formal neuron is a mathematical and computational presentation of a biological neuron (McCulloch and Pitts 1943); it is a simple unit able to carrying out some elementary calculations. A large number of these units are then connected together, and an attempt is made to determine the computing power of the network thus obtained.

The formal neuron is therefore a mathematical modeling that mimics the functioning of the biological neuron, in particular the summation of inputs, at a biological level, synapses do not all have the same “value” (the connections between the neurons being more or less strong). McCulloch and Pitts (1943) and Rosenblatt (1958) created an algorithm that weights the sum of its inputs by synaptic weights (weighting coefficients). In addition, the 1 s and −1 s at the input are used

there to represent an excitatory or inhibitory synapse, Fig. 2 is a graphical presentation of the formal neuron. The self-organizing map represents a specific type of artificial neural network where its main utility is to map to study and map the distribution of data in a large-dimension, thus, its application can provide many computational advantages in Geosciences even its learning process is unsupervised.

Overview of Artificial Neuron Characteristics

A connectionist network is composed of neurons, which interact to give to the network its global behavior (Tian et al. 2021). In connectionist models, these neurons are elementary processors whose definition is made in analogy with nerve cells (Le Cun 1985). These basic units receive signals from outside or from other neurons in the network, they calculate a function, usually simple, of these signals and in turn send signals to one or more other neurons or to the outside. A neuron is characterized by three parameters: its state, its connections with other neurons, and its transition function (Anderson and Rosenfeld 1988).

The State

An artificial neuron is an element that has an internal state, in fact, it receives signals that eventually allow it to change its state (MacLeod 2021). We will denote S_i the set of possible states of a neuron. It could be for example $\{0, 1\}$, where 0 will be interpreted as the inactive state and 1 the active state (Tian et al. 2021).

Self-Organizing Maps, Fig. 3 Presentation of a neuron (Mejia 1992)

The state S_i of the neuron is a function of the inputs $S_1, \dots, S_n$. The neuron produces an output, which will be transmitted to the connected neurons. To calculate the state of a neuron we must therefore consider the connections between this neuron and other neurons (Fig. 3).

Connections Between Neurons or Architecture

A connection is an established link between two neurons; connections are also called synapses, in analogy with the name of the connectors of real neurons. A connection between two neurons has an associated numerical value called the connection weight. The connection weight W_{ij} between two neurons j and i can take discrete values in $\mathbb{Z}$ or continuous in $\mathbb{R}$. The information passing through the connection will be affected by the value of the corresponding weight. A connection with a weight $W_{ij} = 0$ is equivalent to no connection.

The Transition Function

We are interested here in neurons that calculate their state from the information they receive. We will use the following notation below:

S : The set of possible states of neurons

X_i : The state of a neuron i , where $X_i \in S$.

A_i : The activity of neuron i

W_{ij} : The weight of the connection between neurons j and i

The activity of a neuron is calculated according to the states of the neurons in its neighborhood and the weights of their connections, according to the following formula:

$$A_i = \sum_j W_{ij} X_j \quad (1)$$

The state of a neuron i is a function of the states of neurons j , of its neighborhood, and of the weights of the connections W_{ij} , this function is called the transition function.

These elements are assembled according to certain architecture of a network. This architecture defines a composition of elementary functions that can be used in several ways during the operation of the network; this is called dynamic of a network (Mejia 1992).

Overview of Topologies of Neural Networks

There are several topologies of neural networks:

Multilayer Networks

They are organized in layers. Each neuron generally takes as input all the neurons of the lower layer (Fig. 4). They do not have cycles or intra-class connections. We then define an input layer, an output layer, and n hidden layers (Mejia 1992).

Self-Organizing Maps, Fig. 4 Multilayer perceptron with one hidden layer

Networks with Local Connections

A neuron is not necessarily connected to all the neurons of the previous layer (Fig. 5)

Recurrent Connection Networks

We always have a layered structure, but with returns or possible connections between neurons of the same layer (Fig. 6)

Networks with Complete Connections

All neurons are interconnected (Fig. 7) (Karacan 2021).

Self-Organizing Maps, Fig. 5 Neural network with connections

Self-Organizing Maps, Fig. 6 Neural network with recurrent connections

Self-Organizing Maps, Fig. 7 Neural network with complete connections

Definition of Learning and Overview of Modes

One of the most interesting characteristics of neural networks is their ability to learn. Learning will allow the network to modify its internal structure (synaptic weights) to adapt to its environment (Rumelhart and Mc Clelland 1986)

In the context of neural networks, a network is defined by its connection graph and the activation function of each neuron. Each choice of synaptic coefficients (weights of connection) corresponds to a system, the learning operation is the seeking of the best weights that solve a given problem. To be able to evaluate a particular system, we make a series of experiments to observe the behavior of the network. An experiment is the presentation of the input to the system; the response is collected at the output. The network is evaluated by the value of an error function; a learning problem is then to find a network that minimizes this function.

Learning Modes

We distinguish three learning modes: supervised, unsupervised and reinforced learning.

Supervised Learning

In this mode, a teacher who is perfectly familiar with the desired or correct output guides the network by teaching it the right result at each step. The supervised learning consists to compare the obtained result by the artificial network with the desired output, then to adjust the weights of the connections to minimize the difference between the calculated and the desired output (MacLeod 2021).

Unsupervised Learning

In the unsupervised learning, the network modifies its parameters taking into account only local information. This learning doesn't need any predetermined desired outputs. Networks using this technique are called self-dynamic networks and are considered to be regularity detectors because the network

learns by detecting the regularities in the structure of the input patterns and produces the most satisfactory output.

Reinforced Learning

It is used when the feedback on the quality of performance is provided, the desired output is not completely specified by a teacher. So learning is less directed than supervised learning. Unlike unsupervised learning where no feedback is given, the reinforced Learning Network can use the reinforcement signal to find the most needed desirable weights.

Concept and Construction of Self-Organizing Maps

Self-adaptive or self-organizing map is a class of artificial neural network based on unsupervised learning mode (Tian et al. 2021). It is often referred to by the English term Self-Organizing Map (SOM), or even Teuvo Kohonen's map named after the statistician who developed the concept in 1992.

They used a map in the space to study the distribution of data in a large-dimension. In practice, this mapping can be used to perform discretization, vector quantization, or classification tasks (Silversides 2021). These intelligent data representation structures are inspired, like many other creations of artificial intelligence, from human biology (MacLeod 2021). They involve reproducing the principle of the vertebrate brain: stimuli of the same nature excite a very specific region of the brain. Neurons are organized in the cortex to interpret every kind of imaginable stimuli. In the same way, the self-adaptive map is deployed in order to represent a set of data (Wen et al. 2021), and each neuron represents a very particular group of data according to the common characteristic that bring them together. It allows a multi-dimensional visualization of crossed data. The map performs vector quantization of the data space, it means discrediting the space and dividing it into zones. A significant characteristic called the referent vector is assigned to each zone. The space V is divided into several zones and W_r presents a referent vector associated with a small area of the space V_r and $M, r(2,3)$ presents its associated neuron in the grid A (Fig. 8). Each area can be easily addressed by the indexes of the neurons in the grid (Kohonen 1992 1998).

From an architectural point of view, a Kohonen's self-organizing maps is made up of a grid (most often one-dimensional or two-dimensional). In each node of the grid there is a neuron. Each neuron is linked to a referent vector, responsible for an area in the data space (called the input space) (see Fig. 8). In a self-organizing map, the referent vectors provide a discrete representation of the input space. They are positioned in such a way that they retain the topological shape of the entry space. By keeping the neighborhood

relations in the grid, they allow an easy indexing (via the coordinates in the grid). This is useful in various fields, such as classification of textures, data interpolation, visualization of multidimensional data (Silversides 2021). Let A the rectangular neural grid of a self-organizing map. A neuron map assigns to each input vector V a neuron designated by its position vector, such that the reference vector W_r is closest to V .

Mathematically, we express this association by a function (Kohonen 1992):

$$\varphi_m : V \rightarrow A \quad (2)$$

$$r = \phi_m(v) = \arg \min_{r \in A} \|v - w_r\| \quad (3)$$

This function allows us to define the applications of the card. For the quantifier vector, we approximate each point in the input space by the closest referent vector by:

$$W_r = \varphi_m^{-1}(\varphi_w(v)) \quad (4)$$

For the classifier we use the function $r = \phi_w(v)$. Each neuron in the grid is assigned a label corresponding to a class. All the points of the entry space which are projected on the same neuron belong to the same class. The same class can be associated with several neurons.

The learning algorithm is based on the concept of the winner neuron, after a random initialization of the values of each neuron, the data are submitted one by one to the self-adaptive map (Agterberg and Cheng 2022). Depending on the values of the neurons, there is one that will respond best to the stimulus (the one whose value will be closest to the data presented). Then this neuron will be rewarded with a change in value so that it responds even better to another stimulus of the same nature as the previous one. In the same way, the neurons neighboring the winner are also somewhat rewarded with a gain multiplying factor of less than one. Thus, it is the entire region of the map around the winning neuron that specializes. At the end of the algorithm, when the neurons no longer move, or very little, at each iteration, the self-organizing map covers the entire topology of the data (see Fig. 9)

Self-Organizing Maps, Fig. 8 Self-Organizing maps architecture

Self-Organizing Maps, Fig. 9 Self-organization algorithm for the Kohonen model

The mapping of the input space is carried out by adapting the referent vectors W_r . The adaptation is made by a learning algorithm whose power lies in the competition between neurons and in the importance given to the notion of neighborhood.

A random sequence of input vectors is presented during training. With each vector, a new adaptation cycle is started. For each vector V in the sequence, we determine the winning neuron, i.e., the neuron whose referent vector approaches V as best as possible:

$$S = \varphi_m(v) = \arg \min_{r \in A} \|v - W_r^t\| \quad (5)$$

The winning neuron S and its neighbors (defined by a neighborhood membership function) move their referent vectors to the input vector

$$W_r^{t+1} = W_r^t + \Delta W_r^t \quad (6)$$

With

$$\Delta W_r^t = \varepsilon \cdot h(v - W_r^t) \quad (7)$$

where $\varepsilon = \varepsilon(t)$ represents the learning coefficient and $h = h(r, s, t)$ the function which defines membership in the neighborhood (Sreevalsan-Nair 2021).

The learning coefficient defines the amplitude of the overall displacement of the map. The notion of neighborhood is inspired from the cortex, where neurons are connected to each other. This is the topology of the map. The shape of the map defines the neighborhoods of the neurons and therefore the links between neurons. The neighborhood function describes how the neurons in the vicinity of the winner are drawn into the corrective movement (Sreevalsan-Nair 2021). In general, we use:

$$h(r, s, t) = \exp\left(-\frac{\|r - s\|}{2\sigma^2(t)}\right) \quad (8)$$

Where σ is called the neighborhood coefficient. Its role is to determine a neighborhood radius around the winning neuron. The neighborhood function h forces neurons in the neighborhood of S to move their referent vectors closer to the input vector V (Sreevalsan-Nair 2021). The closer a neuron is to the winner in the grid, the less its displacement is important. The correction of referent vectors is weighted by the distances in the grid. This reveals, in the input space, the order relations in the grid.

During learning, the map described by the referent vectors of the network evolves from a random state to a state of stability in which it describes the topology of the input

space while respecting the order relations in the grid (Kohonen 1998).

Application to Petroleum Geosciences

In petroleum exploration and production, the prediction of lithofacies is an important issue, where lithofacies is the first task to identify in petroleum reservoir characterization in order to determine layer limits of a crossed formation of a well and geological rock type using petrophysical recordings crossed a well named well-logs data with core analysis. The recuperation of core is an expensive process and not always continuous (Chen and Zhang 2021).

Here, we show the efficiency of self-organizing maps to predict lithofacies from raw well-logs data of two boreholes named Well01 and Well02, located in the Algerian Sahara.

Raw well-logs data are: Natural Gamma ray, Natural Gamma ray spectroscopy (Thorium, Potassium and Uranium concentration), Bulk density, Neutron porosity, Photoelectric absorption coefficient and Slowness of the P wave. Figure 10 presents these raw logs data versus the depth, only the depth interval [3410 m, 3505 m] is investigated with a sampling interval of half a foot and the obtained lithofacies using the natural Gamma ray log (see track 02). In this case we take the following criteria: $0 < \text{Gamma ray} < 30$ is a sandstone; $30 < \text{Gamma ray} < 60$ is a Clayey Sand $60 < \text{Gamma ray} < 90$ is a Sandy; Gamma ray > 90 is a Clay.

Raw well-logs are injected in a self-organizing map composed of 08 neurons in the input layer and 04 neurons in the output layer, the goal is to train this map, at the end of the learning weights of connection between neurons are optimized. The obtained lithofacies using the Gamma ray log are used to index the map and one of the following four lithologies: Clay, Sandstone, Clayey Sandstone, Sandy Clay, is attributed to each class number. After the learning stage, Raw well-logs data of the two wells are propagated through the machine using the optimized weights of connection.

Figure 11 shows the obtained lithofacies using the Gamma ray log (track A) and the implemented Kohonen Self-Organizing map.

Conclusions

Self-Organizing Maps (SOMs) is a class of neural network based on the unsupervised learning, they are used to map a real space, to study the distribution of data in a large-dimension and involve reproducing the neuronal principle of the vertebrate brain. SOMs are based on the principle of neighborhood and winner neuron. Application to real well-logs data proves the power of the SOMs to classify

Sensitivity Analysis

Valentina Ciriello¹ and Daniel M. Tartakovsky²

¹Dipartimento di Ingegneria Civile, Chimica, Ambientale e dei Materiali (DICAM), Università di Bologna, Bologna, Italy

²Department of Energy Resources Engineering, Stanford University, Stanford, CA, USA

Definition

Sensitivity analysis (SA) is a procedure used to rank the various input components by the degree to which changes in their values impact the model output. The input may include model parameters, boundary and initial conditions, and model assumptions. SA has become an integral part of mathematical

modeling (e.g., Razavi et al. 2021). It is used to estimate the robustness of model calibration, to reduce the input space's dimensionality for subsequent uncertainty quantification, and to guide data collection campaigns or system design (e.g., Ciriello et al. 2015; Um et al. 2018) or decision-making under uncertainty (e.g., Tartakovsky 2013).

Local Sensitivity Analysis (LSA)

Suppose that a model input $\mathbf{p}$ consists of N_{par} components $\mathbf{p} = \{p_1, \dots, p_{N_{\text{par}}}\}$. Model calibration consists of identifying an input $\mathbf{p}^* = \{p_1^*, \dots, p_{N_{\text{par}}}^*\}$ —a point in the input space Ω_p of all possible combinations of the input $\mathbf{p}$ —that minimizes a discrepancy between the model predictions and observations. LSA is a suite of techniques whose aim is to gauge the impact of a slight deviation $\delta\mathbf{p}$ from the point or “locale” $\mathbf{p}^*$ on the model output (Fig. 1); the components p_i ($i = 1, \dots, N_{\text{par}}$) are ranked by the magnitude of change in the model output due to the change from p_i^* to $p_i^* + \delta p_i$, while keeping the remaining components p_k ($k \neq i$) fixed at their respective values p_k^* . LSA remains popular in geosciences because of its ease of implementation and scalability with N_{par} . Yet, it has a number of shortcomings and limitations.

First, the ubiquitous data scarcity and spatiotemporal variability of the input $\mathbf{p}$ often undermine the reliability of model calibration efforts by rendering the “optimal” model parameterization, i.e., the identification of the point $\mathbf{p}^*$, nonunique. Second, the existence of alternative metrics of the discrepancy between model predictions and observations, e.g., root mean square error or mean absolute error, serves as an additional source of nonuniqueness of model calibration (Fig. 1). The absence of a uniquely defined point $\mathbf{p}^*$ undermines *raison d'être* for LSA. Third, in its standard form, LSA assumes both model predictions and observations to be error-free (deterministic). That assumption seldom, if ever, holds in geosciences due to pervasive uncertainty.

Global Sensitivity Analysis (GSA)

GSA overcomes these limitations by adopting the probabilistic framework and equipping each input component, p_i , with its range of variability, $[p_i^{\min}, p_i^{\max}]$, and with a probabilistic model (i.e., cumulative distribution function F_{p_i}) defined on that range. The choice of the ranges and distributions is subjective and reflects the degree of uncertainty in input values. Rather than focusing on small deviations from a single point $\mathbf{p}^*$ one input element at a time, GSA allows the input $\mathbf{p}$ to span the whole input space $\Omega_p = [p_1^{\min}, p_1^{\max}] \times \dots \times [p_{N_{\text{par}}}^{\min}, p_{N_{\text{par}}}^{\max}]$ simultaneously (Fig. 1). In doing so, GSA makes no assumption about either uniqueness or optimality of a

Sensitivity Analysis, Fig. 1 Left: Local sensitivity analysis is conducted by perturbing the calibrated input set $\mathbf{p}^*$ by a small amount $\delta \mathbf{p}$. The point $\mathbf{p}^*$ is nonunique, depending, among other things, on the choice of the discrepancy metric (e.g., root mean square error or mean

absolute error) between model predictions and observations. Right: Global sensitivity analysis allows the input $\mathbf{p}$ to span the whole range of its possible values

particular set of parameters obtained via calibration. GSA estimates the degree to which each random (uncertain) input component, p_i , and interactions between different components, p_i and p_k with $i \neq k$, contribute to uncertainty in the model predictions. The past decades witnessed the widespread adoption of GSA by the computational community, including in geosciences (Ferretti et al. 2016).

Variance-based GSA quantifies the predictive uncertainty of a model in terms of the variance of the model output. Thus, the Sobol' indices, the most widely used GSA metrics, rely on the analysis of variance (ANOVA) to apportion the output variance among the variances of the input components and their interactions (e.g., Ciriello et al. 2015; Ferretti et al. 2016). Variance-based GSA is strictly applicable to uncorrelated random inputs. Its application to systems, whose input components are correlated random fields and/or are mutually correlated, is valid as an uncontrollable approximation. This limitation can be overcome by deploying the Rosenblatt transform to map correlated input components onto independent, identically distributed random variables (e.g., Um et al. 2019, and references therein).

Variance-based GSA is of limited value for the systems with highly non-Gaussian (e.g., multimodal) input and output. Such problems call for the use of distribution-based GSA techniques. Examples of the latter include analysis of the difference between the unconditional distribution of the output and its conditional counterparts when one or more inputs are fixed (e.g., Ciriello et al. 2019), and information-theoretic approaches and Bayesian networks (e.g., Um et al. 2019).

By identifying the most influential factors governing a given system, these and other variants of GSA can be used to guide data acquisition campaigns and monitoring activities; additional data collected on the basis of GSA findings narrow the degree of uncertainty in model output (Ciriello et al. 2015).

Numerical Implementation of GSA

GSA is typically performed via Monte Carlo simulations, which can be prohibitively expensive for complex models common in geosciences. A viable solution to this problem is to use surrogates (emulators). A surrogate is a computationally efficient model, such as a polynomial function or a deep neural network (e.g., Zhou and Tartakovsky 2021, and references therein), which is calibrated on a dataset generated by running the original model multiple times.

Polynomial chaos expansions (PCEs) are used to construct surrogate models and to accelerate variance-based GSA (e.g., Ciriello et al. 2017). For example, Sobol' metrics can be expressed as an analytical post-processing of PCE coefficients, drastically reducing the computational cost of variance-based GSA (Sudret 2008). PCEs also allow one to accelerate the numerical implementation of distribution-based GSA (Ciriello et al. 2019).

Summary

Decision-making under uncertainty in geosciences benefits from the use of SA as part of mathematical modeling. SA can be applied both in forward and inverse uncertainty quantification problems. The increasing adoption of GSA in geosciences is associated with the adoption of surrogate modeling techniques and/or efficient and robust algorithms, which drastically reduce the computational cost associated with the definition of global sensitivity metrics.

Sequence Classification

Mehala Balamurali

Australian Center for Field Robotics, University of Sydney, Sydney, NSW, Australia

Definition

In general, a sequence can be defined as a series of events that are happened in order. These events can be arranged as a simple symbolic values, a vector of complex sequence, and a time series sequences where a single or multiple numerical vectors associate with timestamps or any other complex data types (Xing et al. 2010). In machine learning, sequence analysis is used for inferring the next value, the class label of sequence, or the next sequence based on the prior pattern of the data in the sequence. Sequence classification is a method to infer the class label of unseen sequence by training the classification model with labeled sequence data.

Sequence Classification in Geosciences

In geology, layers of sediment deposits are known as stratigraphic sequences. Stratigraphic data and geophysical logs

provide information about the deposits and the seismic sequences. Hidden Markov models are used to classify log facies and identify seismic events by considering the transition probability from one facies to another, where the unspecified facies profiles are considered as a sequence of unknown states. The model utilizes expectation–maximization algorithm to estimate the unknown parameters (Lindberg and Grana 2015; Cárdenas-Peña et al. 2013).

Random forests (RF) and support vector machines (SVM) are successfully applied in other classification tasks such as geochemical and material classifications. Of these studies, RF and SVM methods have been adopted in identifying and classifying pattern in sequential data. Cracknell and Reading (2013) compared the performance of RF and SVM to categorize high-grade meta-sedimentary and meta-volcanic rocks of the Broken Hill region, Australia, using airborne geophysical and Landsat multispectral imagery. SVM was found superior to other supervised and unsupervised methods in classifying lithofacies using the combined well log data from Devonian Bakken and Mahantango-Marcellus (Bhattacharya et al. 2016). SVM incorporating dynamic time warping DTW feature extractor has been used for classifying time series data (Gudmundsson et al. 2008).

Many studies have been conducted, on the development of automatically classified geophysical log data based on machine learning applications. However, choosing the optimal features that can classify signatures from the signals is difficult in traditional machine learning techniques. Unlike machine learning techniques, deep learning models can automatically learn the optimal features through multiple stages of learning. Among them RNN (Tang et al. 2016; Chung et al. 2014) is an effective neural network for sequence analysis, such as natural language processing, speech recognition, and music generation. Long short-term memory or LSTM (Hochreiter and Schmidhuber 1997) networks are a special kind of RNNs that deal with the long-term dependency problem effectively. These models have been successfully used to extract the sedimentary facies information from well logs (Song et al. 2020). The aptitude of bidirectional long short-term memory (Bi-LSTM) was tested for retrieving information and text mining from the geoscience reports (Qiu et al. 2018).

One-dimensional CNN models were successfully applied in many sequence analysis problems such as solving inversion of electromagnetic problem (Puzyrev and Swidinsky 2021) and classifying hyperspectral data that are used in various applications of geosciences and remote sensing (Wei et al. 2019). A combination of deep CNN model with LSTM and RF has shown promising results on simulating the dynamics of land use change (Xing et al. 2020).

The following section briefly describes the sequence classification methods using deep learning. Please refer the entries in this book for other machine learning algorithms

that are used in sequence classification: random forest, neural network, Markov chains.

Sequence Classification Using Deep Learning Algorithms

Deep neural network (DNN) models are compelling machine learning algorithms that showed promising results on difficult tasks such as image classification, speech recognition, and object detection. DNNs are flexible, powerful, and they work well when there is enough ground truth data, but their applicability is limited for analyzing sequences because their inputs and targets need to be sensibly programmed as fixed dimensionality vectors. Many real-world problems are happened as sequential events where the length of event is unknown so as their dimensions. Below are some deep learning algorithms that are successfully applied in sequence learning.

Recurrent Neural Networks (RNNs)

Unlike traditional neural network, recurrent neural networks have loop in them. Hence the model allows the cells to continue the information to adjacent cells (Fig. 1). As RNNs can remember the features of preceding inputs and outputs, the model is much suitable for inferring the information of following sequence. However, the model cannot learn the longtime dependency of the sequence.

LSTM Networks

Long short-term memory networks are a special kind of recurrent network that can handle the long-term dependencies effectively by removing the limitation of RNN, such as gradient vanishing and exploding, complex training, and difficulty to process very long sequences. Similar to standard RNN, LSTMs are made of chain of repeating modules.

However, the module of LSTM has multiple recurrently connected memory cells and three multiplication units: a forget gate, input gate, and output gate (Graves and Schmidhuber 2005).

As seen in the Fig. 2, the classification network consists of a sequence input layer, LSTM layer, fully connected layer, a SoftMax layer, and an output layer. The model can be further deepening by introducing additional LSTM layers. Furthermore, LSTM combined with CNN layers can be used for analyzing video or time-stamped images where CNN is used to learn the spatial information.

LSTM networks can be used for sequence-to-label classification and sequence-to-sequence classification. In **sequence-to-label classification**, the network is trained with different sequences and the corresponding label for each sequence. The trained model is then used to classify the unseen sequences. In **sequence-to-sequence classification**, the network is trained with a single sequence X_{Train} that can have multiple dimensions and the corresponding sequence of categorical labels Y_{Train} . The trained model can make prediction on every time step with categorical label.

1D CNNs

Figure 3 shows an architecture of 1D CNN that is used to classify sequences. The convolution layer in this model uses 1D filters/kernels to process the input data. Similar to 2D and 3D CNN models, 1D coevolution blocks also include activation function and pooling layers. Please refer ▶ “Deep CNN-Based AI for Geosciences” for further details.

Summary

Machine learning algorithms have emerged as useful tools in geosciences that provide researchers with openings for

Sequence Classification, Fig. 1 Recurrent neural network (RNN) and its unfold version

Sequence Classification, Fig. 2 Layers in the classical network

Sequence Classification, Fig. 3 Architecture of CNN model for classifying hyperspectral data (Qamar and Dobler 2020)

improved prediction, interpretation, anomaly detection, event classification, and hence contribute to better decision-making. Growing technology facilitates these methodologies by further offering fast computation and better storage for large data. The models demonstrated in this chapter are some of the machine learning applications that are extensively valid in geological investigations where the data can be represented as a series of events that are happened in order.

Sequential Gaussian Simulation

J. Jaime Gómez-Hernández

Research Institute of Water and Environmental Engineering
Universitat Politècnica de València, Valencia, Spain

Definition

Sequential Gaussian simulation is a computer-based technique for the generation of realizations $z(\mathbf{x})$ from a multi-Gaussian random function $Z(\mathbf{x})$ defined on a finite point set D , generally discretizing into N voxels a one-, two-, or three-dimensional area of interest. There are many other techniques capable of generating realizations from a multi-Gaussian random function, but what makes unique the sequential Gaussian simulation algorithm is the possibility of generating realizations with a reasonable computing effort over arbitrarily large domains with N easily reaching values larger than millions. This is achieved thanks to the sequential simulation principle derived and implemented by André Journel's group at Stanford University in the late 1980s (Gómez-Hernández and Srivastava 2021).

Random Function

A random function $Z(\mathbf{x})$ can be defined as a rule that assigns a realization to the outcome of an experiment

$$Z(\mathbf{x}) \sim \{z(\mathbf{x}, \theta)\}, \forall \theta \in \Omega, \mathbf{x} \in \mathcal{D}. \quad (1)$$

In the case of numerical simulations in discretized domains, D is defined as the set of N points falling at the

centers of the voxels discretizing the area of study; $\mathbf{x}$ is any such point, θ is the outcome of an experiment, and Ω is the sample space containing all possible outcomes. In the remainder, the dependency of any realization on θ will be dropped and lower capital letters will be used to refer to a realization or the values it could take, and upper capital letters will be used for random variables or random functions.

A random function can also be defined by all the n -variate distributions

$$F(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n; z_1, z_2, \dots, z_n) = \text{Prob}(Z(\mathbf{x}_1) \leq z_1, Z(\mathbf{x}_2) \leq z_2, \dots, Z(\mathbf{x}_n) \leq z_n), \quad (2)$$

for any subset of n points out of the N points discretizing the study area. In the previous expression, $Z(\mathbf{x}_i)$ is a random variable defined at $\mathbf{x}_i$ through the ensemble of realizations.

When the random function is multi-Gaussian, each random variable can take any value in $\Re$ and the distributions in Eq. (2) have the following expression (Anderson 1984)

$$F(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n; z_1, z_2, \dots, z_n) = (2\pi)^{-\frac{n}{2}} \left| \Sigma \right|^{\frac{1}{2}} \int_{-\infty}^{z_1} \int_{-\infty}^{z_2} \dots \int_{-\infty}^{z_n} e^{-\frac{1}{2}(\mathbf{z}-\boldsymbol{\mu})^T \Sigma^{-1}(\mathbf{z}-\boldsymbol{\mu})} d\mathbf{z}, \quad (3)$$

where $\boldsymbol{\mu}$ is a column vector with the expected values of the random variables

$$\boldsymbol{\mu} = \begin{Bmatrix} E\{Z(\mathbf{x}_1)\} \\ E\{Z(\mathbf{x}_2)\} \\ \dots \\ E\{Z(\mathbf{x}_n)\} \end{Bmatrix}, \quad (4)$$

$\mathbf{z}$ is an n -component column vector with the integration variables, and Σ is a matrix of covariances

$$\Sigma = \begin{pmatrix} C(Z(\mathbf{x}_1), Z(\mathbf{x}_1)) & C(Z(\mathbf{x}_1), Z(\mathbf{x}_2)) & \dots & C(Z(\mathbf{x}_1), Z(\mathbf{x}_n)) \\ C(Z(\mathbf{x}_2), Z(\mathbf{x}_1)) & C(Z(\mathbf{x}_2), Z(\mathbf{x}_2)) & \dots & C(Z(\mathbf{x}_2), Z(\mathbf{x}_n)) \\ \vdots & \vdots & \ddots & \vdots \\ C(Z(\mathbf{x}_n), Z(\mathbf{x}_1)) & C(Z(\mathbf{x}_n), Z(\mathbf{x}_2)) & \dots & C(Z(\mathbf{x}_n), Z(\mathbf{x}_n)) \end{pmatrix}. \quad (5)$$

The attractiveness of the multi-Gaussian distribution is that it is fully characterized by its expected value and its covariance between any two points in its domain. At the same time, this is its major drawback since such a characterization prevents any control on the higher-order moments, which are fully determined as functions of the mean and covariance. Once a multi-Gaussian random function is chosen, the user

cannot expect higher-order moments different from the ones to be derived from the distributions in Eq. (3). For instance, multi-Gaussianity will always prevent high continuity of extreme values, a property much desirable in the geosciences when modeling fracture zones or impermeable shale barriers.

Sequential Gaussian Simulation, Fig. 1 Estimation versus simulation. Top row, sample data and estimated map obtained by kriging. Bottom row, three realizations. All maps conditioned to the sample data and corresponding to the same random function

Estimation Versus Simulation

The behavior of a random function can be analyzed by looking at the average value of all the realizations that compose it or by looking at an ensemble of individual realizations.

When talking about estimation, the stack of realizations that make up the random function is collapsed into a single spatial function obtained by averaging, point by point, all the realizations. Equivalently, this would be the same as computing the expected value of each random variable, and this is what kriging does. Such a representation is locally optimal in some sense (Journal 1989), meaning that, focusing on a single location and computing the deviation of the expected value from all possible values in the ensemble of realizations, the mean deviation would be zero and its variance would be minimal. This does not mean that the spatial representation is realistic; in fact, the mean value will not coincide with any specific realization, but rather it will display lower variance and a more continuous, smoother spatial variability than any specific realization. Figure 1 shows, on the top row, a set of 64 data and the resulting estimated map obtained by kriging.

While estimation seeks a locally optimal estimate of the attribute, simulation seeks to generate alternative realizations from the random function. These realizations have specific patterns of variability and continuity. Figure 1 shows, on the bottom row, three realizations from the ensemble of realizations that make up the random function, the average of which

is the kriging map on the top row. It is evident that there is more variability in any of the realizations than in the estimated map both in terms of variance and in terms of spatial correlation. In fact, any of the realizations could be the reality that stands behind the 64 sample data.

When should estimation be used instead of simulation or vice versa? The answer is simple, if the resulting map is going to be used to compute some kind of attribute that is a linear combination of the map values, a kriging estimate is good enough. This is the case when computing the total reserves in a mine, and the random function is used to model ore grades. However, if the map is going to be used to compute a response variable that depends non-linearly on the attribute, as it would be the case of computing the travel time of a contaminant traversing an aquifer in which the property mapped is hydraulic conductivity: the time that the contaminant would take to cross the aquifer on the estimated map of Fig. 1 will be very different from the time computed as the average of the times that the contaminant takes to cross each one of the realizations in the ensemble.

Sequential Simulation

The sequential simulation algorithm was proposed by André Journé in the late 1980s to address the problem of how to generate a realization from a non-Gaussian random function

defined on the basis of indicator functions (functions that take a value of 0 or 1 depending if the argument is above or below a given threshold). The first publicly available code was published by Gómez-Hernández and Srivastava (1990), and it describes the principles of the algorithm and many implementation issues. Soon after, it was realized that sequential simulation could also be applied for the generation of realizations from other random functions, particularly, from multi-Gaussian random functions, and sequential Gaussian simulation was born (Deutsch and Journel 1992; Gómez-Hernández and Journel 1993).

The basic idea behind sequential simulation is quite simple (Gómez-Hernández and Cassiraga 1994). Given a random function defined over a finite point set of size N , the probability distribution in Eq. (2) can be decomposed, by recursively applying the definition of conditional probability, as follows:

$$\begin{aligned} F(Z(\mathbf{x}_1), Z(\mathbf{x}_2), \dots, Z(\mathbf{x}_N)) &= F(Z(\mathbf{x}_1)) \cdot \\ &F(Z(\mathbf{x}_2)|Z(\mathbf{x}_1)) \cdot \\ &F(Z(\mathbf{x}_3)|Z(\mathbf{x}_1), Z(\mathbf{x}_2)) \cdot \dots \\ &F(Z(\mathbf{x}_N)|Z(\mathbf{x}_1), \dots, Z(\mathbf{x}_{N-1})). \end{aligned} \quad (6)$$

Using this decomposition, drawing a realization from a full N -variate distribution can be replaced by drawing, sequentially, N values from N conditional univariate distributions. The only requirement would be the ability to compute the conditional distribution of any random variable given any number of random variables, which, for the case of a multi-Gaussian random function, is trivial.

The conditional distribution of a random variable given any number of random variables when these random variables are members of a multi-Gaussian random function is a Gaussian distribution with mean and covariance given by the solution of a set of normal equations (Anderson 1984), also known as the simple kriging equations. Its expression is

$$\begin{aligned} \text{Prob}(Z(\mathbf{x}_i) \leq z_i | Z(\mathbf{x}_1) = z_1, Z(\mathbf{x}_2) = z_2, \dots, Z(\mathbf{x}_n) = z_n) = \\ \frac{1}{\sigma \sqrt{2\pi}} \int_{-\infty}^{z_i} e^{-\frac{(z-\mu)^2}{2\sigma^2}} dz \end{aligned} \quad (7)$$

with μ being the estimate of $z(\mathbf{x}_i)$ using as data $\{z_1, z_2, \dots, z_n\}$ at locations $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n\}$, respectively, and σ^2 the corresponding simple kriging variance.

The conditional distribution in Eq. (7) is generally approximated, when the number n is large, by restricting the data used to solve the kriging equations to a predefined maximum number within a given search neighborhood around $\mathbf{x}_i$. Only the subset of $z_1, z_2, \dots, z_n$ that falls within the neighborhood and only the closest values up to a certain maximum number

are used to build the simple kriging system. This approximation is necessary since, for a realization with N larger than a few hundreds, the decomposition in Eq. (6) results in conditional distributions depending in too many conditioning data; determining the parameters of those conditional distributions would amount to solving kriging systems with hundreds of equations; in order to keep the computation of the conditional realizations – that has to be repeated for each point – at a reasonable computing cost, there is a need to reduce the size of the kriging system, which can be achieved using the concept of a search neighborhood and limiting the maximum number of points.

Sequential Gaussian Simulation Algorithm

Drawing a realization from a multi-Gaussian random function can be achieved as follows:

1. Define a random permutation of the natural numbers 1 to N that will serve to define how expression (6) is built and also the order in which the points will be visited.
2. Following the order in the random permutation, visit each point and
 - (a) Search for the values that have already been simulated falling within a search neighborhood centered at the point to simulated.
 - (b) Solve the simple kriging equations to determine the mean and the variance of the Gaussian conditional distribution.
 - (c) Draw a random number from the conditional distribution and assign it to the point.
3. Return to the beginning for the generation of a new realization.

Remarks

Equation (6) is valid for any permutation of numbers 1 to N ; a random permutation is suggested because it was found that the approximation of the conditional distribution retaining only the closest simulated points introduces some artifacts in the realizations when a structured sequence is used (for instance, simulating the points following the rows or columns of a two-dimensional realization).

Conditional realizations, that is, realizations that honor the observed data at data locations can be generated simply by including their locations in the domain D and by including the observed values as known (already simulated) values at their locations prior to the start of any simulation.

There are other implementation issues, many of which can be consulted in the review paper by Gómez-Hernández and Srivastava (2021). Some of them try to speed up the simulation time, for instance, simulating not one point at a time, but a whole bunch of nearby points at once, or relocating all

observed data and simulation locations over a regular grid that would permit the precomputation of the covariance values that will be repeatedly used to build the kriging systems. Others try to solve conceptual problems, like when the conditioning data do not have a Gaussian histogram, in which case the data should be transformed into normal-scores – where they will have a standardized Gaussian histogram–, sequential Gaussian simulation will be carried out in normal-score space, and the results will be back-transformed to the original space.

Summary and Conclusions

Sequential Gaussian simulation is a stochastic simulation technique to draw realizations from a multi-Gaussian random function. It is a specific implementation of the more general sequential simulation algorithm that could generate realizations from any random function for which the conditional distribution of any random variable given any number of random variables can be determined or approximated. The attractiveness of the multi-Gaussian random function is that it is characterized by a mean and a covariance, parameters that can be decided upon an exploratory data analysis.

Biography

Jean Serra was born in Algeria in 1940, where he lived until 1962. After high school, he studied in France at Nancy School of Mines and received an engineering degree in 1962. He also got a Bachelor degree in philosophy/psychology in 1965 from the University of Nancy.

From 1962 to 1966, while a research engineer at the Iron and steel research institute in France, Serra undertook a Ph.D. under the supervision of Georges Matheron, about geostatistics of iron ore deposit of Lorraine. During that period, Serra came up with the idea of using structuring elements for transforming images of thin cross sections of the ore in order to extract information. This work led to a device called “Texture Analyser,” and the hit-or-miss transformation, which was extended by Matheron to the concepts of erosion, dilation, opening and closing, and granulometry. In 1966, Matheron and Serra decided to give a name to the approach they were developing: “Mathematical morphology.” Jean Serra obtained a Ph.D. in Mathematical Geology from the University of Nancy in 1967, and a Doctorat d’état in Mathematics, from the University Paris-VI in 1986.

In 1968, the Centre of Mathematical Morphology of the École des Mines de Paris was created, combining geostatistics and mathematical morphology (after 5 years, the two groups became independent). The center itself was localized at Fontainebleau, France. Matheron was appointed director, and Serra was hired as master of research (“Maître de Recherches”) and assistant director. This was an important anchoring point. Very soon, the chaining of successive hit or miss transforms were shown to create new and interesting operations. In parallel, the German company Leitz commercialized the texture analyzer. The 1970s correspond to the period where many classical Mathematical Morphology tools were created, including in particular: binary thinning, skeleton by influence zones, ultimate erosion, particle analysis, conditional bisector, morphological gradient, top hat transform and watershed. In 1971, Serra took a sabbatical year at the Lomonosov University, Moscow.

During the 1970s and the 1980s, Jean Serra actively participated to the dissemination of Mathematical Morphology in Europe, the USA, and Australia. At the scientific level, he worked on a new formulation of Mathematical Morphology relying on the framework of complete lattices. In 1986 he officially became the director of a new Centre of Mathematical Morphology, separated from that of Geostatistics.

At the beginning of the 1990s, Jean Serra spent a sabbatical year in Barcelona, Spain, and started to work on multimedia applications. In 1993 he founded the International Symposium for Mathematical Morphology (ISMM). Since this time,

12 other symposia were held. Important contributions related to this period are connections, connected filters, and segmentation. After his retirement, he has been very active in terms of research as a professor Emeritus of ESIEE, Paris.

Beside his scientific activity, Jean Serra is also a musician. He participated to the Russian Liturgical Choir of the Holy Trinity Church, Paris, and is organist for Saint Peter Church of Avon, since 1988. He speaks French, Russian, English, and Spanish.

Shape

Norman MacLeod

Department of Earth Sciences and Engineering, Nanjing University, Nanjing, Jiangsu, China

Definition

Shape – the geometric form of an object’s boundary, outline, or surface independent of its size and distinct from other properties such as material, color, luster, and/or texture.

Introduction

When earth scientists think or speak of shape, they usually reference one of two very different sets of concepts, perceptions and traditions which also differ in important ways from the mathematician’s or geometer’s views on shape. In common speech shape is most often taken to mean the degree to which the outline of an object conforms to the expected pattern of one or more reference shapes (e.g., a circle, triangle, or square in the case of two-dimensional [2D] shapes, a sphere, prism, or cube in the case of three-dimensional [3D] shapes). This analogistic method of describing shape works well so long as the shape being described is regular and matches the expected geometry of the reference shape closely and so long as an appropriate reference shape exists. Unfortunately, many shapes of interest to earth scientists fail to conform to these simple criteria and so remain difficult to characterize or describe using appeals to analogy.

Perhaps the first thing to note is that the concept of shape is distinguished routinely from the concept of size. A reference shape can adopt a wide variety of sizes, but this variation in no way compromises its utility as a basis for the description of simple shapes. In formal shape analysis, the description or measurement of size is almost always distinguished explicitly from the description or measurement of shape. Indeed, one

popular formal definition of shape is those aspects of a form that remain after position, size, and orientation have been removed from consideration (Kendall, 1984). While pragmatic and practical from a computational point-of-view, this widely cited definition suffers from the obvious logical problems that arise from adopting a definition predicated exclusively on what the concept being defined is not. Kendall's definition also assumes agreement can be reached on how to describe, measure, and/or characterize an object's position, size, and orientation.

Those concerned with the analysis of inorganic particle shapes, such as those of sediment grains and crystals, have tended to follow the recommendations of Wentworth (1922) and Sneed and Folk (1958) who considered shape to be a "tri-dimensional characteristic" via reference to its three, orthogonal, linear dimensions: length, breadth (or width), and thickness. Those concerned with analyses of the shapes of organic bodies, such as animals, plants, and/or the fossilized remains thereof, began by adopting the methods of particle analysis to describe shapes. In recent years, though, these practitioners have tended to follow the recommendations of Blackith and Reyment (1971), who regarded form as arising from the combined effects of size and shape and represented both via sets of linear distances between comparable, or landmark, point locations that could be found on all specimens in a sample. These linear distances did not necessarily need to be confined to the specimen's gross dimensions, and their orientation did not need to respect the constraint of orthogonality. Later Bookstein (1991) refined this "morphometric" approach to form analysis by pointing out that the geometric character of the landmarks used previously to define the endpoints of the scalar linear distances could be preserved in a multivariate morphometric-style analysis by using the 2D or 3D point coordinate locations (= paired or triplet scalar linear distances from the origin of a common coordinate system) as direct input into data analysis procedures, usually after a Procrustes-style standardization had been performed to remove patterns of variance that could be attributed to position, size, and orientation from the point coordinate values. This extension of the multivariate morphometric approach is commonly referred to as "geometric morphometrics" in order to distinguish it from its linear distance-based "multivariate morphometrics" precursor.

Naturally, the main distinguishing feature of the particle analysis and morphometric approaches to the characterization of shape revolved around the perceived absence or presence of topographic point locations that could form a logical basis for the comparison of different shapes. Sedimentary and crystal grains have no such privileged and specific point locations that constitute intrinsic aspects of their forms. As a consequence, maximal or Feret distances (Feret, 1930) defined by the length of hypothetical enclosing

2D or 3D boxes (as measured with rulers or calipers) were used to quantify their shapes. But biological forms can and do exhibit such privileged and specific point locations, often in abundance in the case of morphologically similar species. To many biologically trained shape analysts it seemed self-defeating to ignore the implications of the existence of such point locations and forego the opportunity to employ them as a basis for shape comparison irrespective of how this topological comparability arose (e.g., phylogenetic descent, functional convergence). The existence of these privileged landmark point locations in forms of biological interest also accounts for the suspicion – shared by many biological morphometricians – that use of ratio-based shape characterization indices, calculated from linear distance data, amounts to the unwarranted discarding of aspects of information relevant to geometric shape description and analysis in addition to the representational ambiguities such an operation can entail, especially if the numerator and denominator variables are themselves correlated. Adherents to the tradition of sedimentary particle shape analysis have far fewer scruples when it comes to the use of ratio data. Nonetheless, both traditions, or approaches, to shape description/analysis accept data derived from the 2D and 3D outlines of the forms under consideration though, in the case of geometric morphometrics, not without considerable early resistance.

Mathematical Aspects of Shape

To mathematicians, shape is the external boundary, outline, or surface of any closed-form object as opposed to its color, texture, or composition. Mathematical points have positions, but no shape. Mathematical lines and vectors have position, orientation, and magnitude, but no shape. The simplest 2D Euclidean object that has a shape is a triangle (= three-sided polygon). The simplest 3D Euclidean object that has a shape is a pyramid with a triangular base. Both regular and irregular polygons have the property of shape though, in the case of the latter, this can be difficult to describe. Complex, self-intersecting polygons and pyramids exist as mathematical concepts, but cannot exist as real objects in normal two- or three-dimensional Euclidean spaces. According to Kendall's (1984) definition though, these forms could be thought of as having the property of shape. Circles, ellipses, their 3D counterparts, and any form that includes a curve, are not polygons but do have the property of shape.

One shape may be transformed into another shape by sequences of rotations, translations, and/or reflections. These transformations may be applied isotropically (uniformly in all directions) or anisotropically (non-uniformly in direction). Depending on the character of their transformation sequence,

shapes may be said to be congruent, similar, isotropic, or anisotropic. The mirror transformation of a non-isosceles shape is not usually regarded as being congruent with the original shape as there is no way to devise a sequence of translations or less than 360° rotations that will produce a perfect superposition.

Form Ratios, Form Factors, and Particle Shape Spaces

By the 1920s, it was realized that simple ratios of length variables could be used to define broad categories of particle shapes more objectively and repeatably than text-based descriptions. Wentworth (1922) and Zingg (1935) based their calculations on three objective distance measurements: the particle's longest dimension (L_1), longest dimension perpendicular to L_1 (L_2), and longest dimension perpendicular to both L_1 and L_2 (L_3) (Fig. 1a). These definitions suffice for the majority of particles, especially if the (artificial) requirement of all three distances intersecting at a single point is relaxed. Still, their implementation can be ambiguous or counterintuitive for highly symmetrical (e.g., perfect squares or cubes) and very irregular shapes.

Wentworth (1922) used the relation $(L_1 + L_2)/2 L_3$ to express flatness or equancy and r_1/R (where r_1 = the radius of curvature of sharpest edge and R = the mean radius) to express the roundness of beach pebbles collected from two localities on the US east coast. These indices were used to document an inverse relation between pebble roundness and pebble flatness in what was likely the first quantitative particle shape analysis published in the earth sciences. Wentworth's (1922) data were also used to demonstrate that pebble abrasion was linked directly to the intensity of wave action.

Wentworth's (1922) approach to shape description was later expanded by Zingg (1935) in the form of two ratio-based shape indices $i_1 = L_1/L_2$ and $i_2 = L_3/L_2$. These ratios capture aspects of an object's flatness and elongation, respectively. Zingg (1935) used these ratios as the axes of a Euclidean coordinate system within which disk-shaped ($i_1 < 0.667$, $i_2 \geq 0.667$), spherical ($i_1 \geq 0.667$, $i_2 \geq 0.667$), bladed ($i_1 < 0.667$, $i_2 < 0.667$), and rod-like ($i_1 \geq 0.667$, $i_2 < 0.667$) morphotypic shape categories could be defined and portrayed graphically (Fig. 1b). Sneed and Folk (1958) objected to the fact that Zingg's (1935) system had so few shape categories and was composed of unequal ratio ranges. As an alternative, they proposed a shape modeling system based on a ternary chart in which the horizontal and vertical axes represented the ratios L_2/L_1 and $(L_2-L_3)/(L_2-L_1)$ (Fig. 1c). This triangular space was then subdivided into ten morphotypic shape categories using equally spaced boundaries. Later Hockey (1970) showed that Sneed and Folk's (1958) shape space was isomorphic with a ternary shape space in which the vertical and horizontal axes were calculated as L_2/L_1 and $(L_2-L_3)/L_1$, respectively (Fig. 1c).

Both the Zingg (1935) and Sneed and Folk (1958) particle shape spaces and shape categories are still used and each has its adherents who criticize use of the opposite technique because it introduces "distortions," in the form of density heterogeneities, into the resulting shape identifications. This debate was resolved by Blott and Pye (2008) who used sets of computer-generated random blocks to show that both spaces are prone to density-based distortions at the extreme elongate ends of their respective shape spectra. Accordingly, particle shape analysts need to keep these aspects of the Zingg (1935) and Sneed and Folk (1958) shape spaces in mind when using

Shape, Fig. 1 Particle analysis axes, shape factors, and shape spaces. (a). Tridimensional lengths used originally by Wentworth (1922) to quantify particle shape. These lengths are equivalent to the Feret diameters that are used to characterize more irregular shapes. (b). Particle-axes length ratios, the mathematical space, and the particle shape

categories proposed by Zingg (1935). (c). The triangular particle shape space and shape categories proposed by Sneed and Folk (1958) to characterize particle shapes: C (compact), CP (compact-platy), CB (compact-bladed), CE (compact-elongate), P (platy), B (bladed), E (elongate), VP (very platy), VB (very bladed), VE (very elongate)

them to test statistical hypotheses concerning particle shape distributions and/or shape-group distinctions.

Wentworth's (1922) roundness shape index has also been subject to debate and revision over time, especially since the sharpest edge of a particle or grain might not be representative of the degrees of roundness exhibited by all edges along the particle or grain's periphery. In 1932, Wadell proposed the definition of Wentworth's r_1 index be modified to represent the average radius of all the corners of the particle or grain's projected 2D outline using one of two alternative formulae.

$$P_{d1} = \frac{\left(\frac{\sum_{i=1}^n D_i}{n} \right)}{D_r} \quad (1)$$

$$P_{d2} = \frac{n}{\sum_{i=1}^n \frac{D_i}{D_r}} \quad (2)$$

where:

n = number of corners

D_i = diameter of curvature of corner i

D_r = diameter of largest inscribed circle.

In order to facilitate the collection of corner curvature data across a particle's entire outline, Wadell developed a transparent scale of concentric circles that could be placed over a magnified representation of the outline. Subsequently many authors proposed class definitions for a variety of shape categories based on Wadell's (1932) index.

As noted by Blott and Pye (2008), angularity is an aspect of particle shape commonly thought to be the inverse of roundness. Geometrically though, angularity constitutes a distinct geometric concept based on the angles formed by planes bounding corners along the grain's outline or surface rather than the outline or surface's localized curvature. Particle angularity indices have been proposed, but these have proven difficult to implement owing to scale-related factors. Mandelbrot's concept of the fractal dimension represents an attractive alternative to the difficulties that arise in attempting to implement particle angularity measures, but suffers itself from a lack of predictable geometric specificity as well as the absence of a readily interpretable classification scheme for particle shapes that exhibit defined fractal dimension ranges.

Circularity (2D) and sphericity (3D) are aspects of shape related to, but distinct from, roundness and have usually been assessed by comparing the outline of a grain to that of either an inscribed or mean circle or sphere, quantified (where necessary or appropriate) as a ratio of areas, perimeters, or diameters that express the extent of an outline's or surface's deviation from perfect circularity or sphericity. A large number of indices are available to quantify this deviation.

Finally, just as the concept of roundness focuses attention on a specific category of deviations from circularity, the concept of shape irregularity focuses attention on a different, though related, aspect of geometric deviation. In this case, Blott and Pye (2008) suggested that the magnitude of the deviation from 2D circularity for each local concavity and convexity along the projected outline be quantified and summed across the entire outline according to the following equation:

$$I_{2D} = \sum_{i=1}^n \frac{d_{convex} - d_{concave}}{d_{convex}} \quad (3)$$

where:

n = number of irregularity observations

d_{convex} = distance from the center to the largest inscribed circle to the outline's convex hull in the direction of the i^{th} concavity

$d_{concave}$ = distance from the center to the largest inscribed circle to the nearest point in the direction of the i^{th} concavity

In those cases, where d_{convex} is difficult to assess, an estimate can be obtained by taking an average of the distances between the projections that define the localized aspect of the convex hull according to

$$y = \frac{a \cdot \cos A + b \cdot \cos B}{2} \quad (4)$$

where:

n = number of irregularity observations

a & b = distance from the center of the largest inscribed circle to the tip of the projection on either side of the concavity

A & B = angles between a and x and b and x respectively

The Comparison of Shapes: Shape Deformation Grids

Originally the assessment, description, and analysis of biological shapes were accomplished using many of the same conventions, concepts, and tools that had been developed for the sedimentary particle analysis. A dinosaur cranium, for instance, has a length, width, and depth in the same way a limestone cobble does and form ratios that remove size differences among sets of crania can be calculated just as they can for crystal and grain shapes. But owing to the greater degree of morphological complexity displayed by the different bones of a dinosaur cranium, not to mention their spatial arrangement relative to one another, it is exceedingly difficult

to describe or quantify organic shapes adequately if one restricts oneself to the consideration of only the lengths of three mutually orthogonal axes. Moreover, if the mutual orthogonality of the lengths being used to describe and/or quantify shape cannot be maintained, it becomes exceedingly difficult to recall how the distances being used to describe or quantify the organic shapes in question relate to one another, either in the tables of descriptive characteristics published in the primary taxonomic literature or in the matrices of values analyzed using numerical methods.

In an early attempt to overcome this problem, the Victorian biologist and classics scholar D'Arcy Wentworth Thompson (1917) developed a method – possibly based on Albrecht Dürer's graphical studies of proportional variation in human faces – of representing shape transformations between different vertebrate species by recording the positions of sets of topologically corresponding point locations and summarizing 2D spatial displacements of corresponding point, or landmark, configurations graphically as a smooth deformation of an originally rectilinear grid (Fig. 2a, b). This method of

summarizing shape differences was entirely qualitative and, in a number of cases, not very accurate. But, despite these shortcomings, Thompson's deformation grid approach to the comparison of shapes was highly intriguing in its demonstration that simple sets of smooth deformations could be used to summarize the differences between an astonishing number of radically different shapes. To generations of morphologists, this implied that gaining an understanding of simple variations in the (presumably) small number of geometric variables that controlled the spatial deformation systems responsible for changes in organismal morphology was all that would be needed to understand the perplexing morphological diversity of life.

Thompson was unable to develop mathematical methods that could be used to quantify his deformation-grid approach to the description and comparison of organic shapes. The form ratio and form factor methods developed by the particle and grain analysts were also unsuited to this task because of the limitations imposed by mutual orthogonality and the small number of variables employed in particle shape

Shape, Fig. 2 The characterization of shape change by means of a deformation grid. (a). D'Arcy Thompson's image of the fish genus *Argyropelecus* with a superimposed rectilinear grid. (b). d'Arcy Thompson's image of the fish genus *Sternoptyx* with a sheared and antero-posteriorly compressed version of the *Argyropelecus* grid that appears to bring the major features of the *Sternoptyx* morphology into comparative alignment with those of *Argyropelecus*. Thompson used

this graphic device to argue that even radical morphological differences could be the result of simple geometric transformations. (c). A contemporary mathematical realization of the deformation grid shape transformation between *Argyropelecus* and *Sternoptyx* based on 16 common landmark positions and calculated as a thin-plate spline. Fish images redrawn from Thompson (1917)

characterization. The American quantitative biologist F. L. Bookstein made an early attempt at quantifying Thompson's ideas with his biorthogonal grid technique (Bookstein 1978). Nonetheless, by 1991 a reasonably full, mathematically elegant, and highly useful reconceptualization of what polygonal shapes were from a mathematical point of view, and how they could be represented in a Thompson-esque manner, had been developed, largely as the result of noteworthy contributions by the British statistician David Kendall, Bookstein, and the American statistician Colin Goodall (see Bookstein, 1993).

The modern (re)formation of the Thompsonian shape deformation grid involves calculating a polyharmonic thin plate spline (TPS), which is related computationally to a form of kriging. This mathematical spline attempts to mimic the behavior of a defect-free, uniform, and infinitely thin metal plate that is bent in the z direction to conform to the geometry of the x,y shape displacement vectors at corresponding locations across the reference and target shapes. The metal plate metaphor is important because, unlike elastic surfaces, metal plates bend in ways that minimize the energy required to achieve the bend in all directions over the entire plate. In applying this physical

metaphor to shape analysis, the TPS represents the surface of minimal bending energy implied by the transformation of one shape into another.

In the TPS calculation, bending energy is quantified by the following expression:

$$U(r_{ij}) = r_{ij}^2 \ln r_{ij}^2 \quad (5)$$

where r_{ij}^2 is the square of the distance between landmarks i and j in the reference shape's landmark configuration and $\ln$ is the natural logarithm. This calculation quantifies the relative amount of "energy" required to achieve a bend between all pairs of landmarks. The spacing of the landmarks represents an important constraint on the spline because it requires more "energy" to achieve a bend between closely spaced landmarks than between landmarks located at a distance from one another.

All possible modes of bending across a set of landmarks are specified by a partitioned matrix (L) whose structure is summarized as follows:

Shape, Fig. 3 The empirical shape space of triangles. (a). Feret diameter shape spaces for collections of left-verging right triangles (white), isosceles triangles (gray), and right-verging right triangles (black). Note that, although these triangles have different shapes, they plot in exactly the same positions in the particle analysis space. This suggests that each point in the spaces used by sedimentary and particle analyses (e.g., Fig. 1b, c) actually corresponds to families of differently shaped objects. (b). Procrustes shape coordinate plots of the triangle sets shown in a. Note that each of the non-congruent triangles has vertices that plot in

unique positions within this space. (c). The 2D covariance-based PCA space of the shape coordinate data shown in b. Note that families of isosceles, and of right- and left-verging right triangles, plot along consistent trajectories within the PC space. (d). The 3D covariance-based PCA space of the shape coordinate data shown in b. Note that the 2D curved trajectories shown in c exhibit a 3D curvature, as if the triangular shapes they represent are located at unique positions along a spherical surface

$$L = \begin{pmatrix} P & Q \\ Q' & 0 \end{pmatrix} \quad (6)$$

The P matrix partition summarizes the distances between landmarks using the U function (Eq. 5).

$$P = \begin{pmatrix} 0 & U_{12} & U_{13} & \dots & U_{1p} \\ U_{21} & 0 & U_{23} & \dots & U_{2p} \\ U_{31} & U_{32} & 0 & \dots & U_{3p} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ U_{p1} & U_{p2} & U_{p3} & \dots & 0 \end{pmatrix} \quad (7)$$

The Q matrix summarizes the coordinates of the reference landmark configuration.

$$Q = \begin{pmatrix} 1 & x_1 & y_1 \\ 1 & x_2 & y_2 \\ 1 & x_3 & y_3 \\ \vdots & \vdots & \vdots \\ 1 & x_p & y_p \end{pmatrix} \quad (8)$$

Finally, the 0 matrix is a 3×3 matrix of zeros. The overall TPS surface is calculated from the L^{-1} matrix by padding the matrix of x and y shape coordinate values for the target configuration (X_t) out with a 3×2 matrix of zeros (X_{t+}) to give it the same number of rows as the L^{-1} matrix and then multiplying these two matrices together as follows:

$$W = L^{-1}X_{t+} \quad (9)$$

This creates a weight matrix (W) which can be used to calculate the z coordinate of the TPS. An example of the result of this calculation for Thompson's example of the shape transformation from *Argyropelecus* to *Sternoptyx* is shown in Fig. 2c.

Geometric Shape Spaces

With regard to the current mathematical concept of shape and its relation to the concept used in particle shape analysis, this is also best illustrated by way of an example. Figure 3a shows three sets of triangles with identical Feret diameters. All three sets display a variety of different shapes, yet all plot at the same positions in the shape space analogous to those used by particle shape analysts. This result shows clearly how and why the conventions used by particle shape analysts are useful for specifying broad classes of similar shapes but cannot be employed in the detailed characterization of shape when information regarding the topological identity of parts or structures is present.

Of course the shapes of these same triangles can also be specified by recording the x, y coordinates of their vertices. Figure 3b shows the superposition of these vertices in the space of the two Procrustes shape coordinates, s_1 and s_2 . Note the clear distinction between the geometries of the isosceles (gray) and left- (white) and right- (black) verging right triangles. Note also that each set of vertex points contains only seven apparent positions. The reason for this apparent reduction is that triangles along the upward trending diagonals of the triangle sets shown in Fig. 3a all have the same aspect ratio and so have the same shapes but different sizes. Therefore, use of corresponding landmark locations is able to represent polygonal shapes correctly, whereas the use of Feret diameters cannot.

Figures 3c, d show results of a covariance-based principal component analysis (PCA) of these Procrustes-aligned shape coordinate data both in terms of the first two (Fig. 3c) and a complete set of three (Fig. 3d) eigenvectors. Each point in this space represents a unique configuration of the six coordinate values that, together, comprise any triangle. But unlike the width/height space (or a PCA-determined representation

Shape, Fig. 4 The mathematical shape space of triangles. All conceivable polygonal shapes of constant size can be located at a unique position on the surfaces of a $2K-3$ dimensional manifold where K = the number of polygon-defining landmarks. In the case of triangles, the dimensionality of this manifold is 3, so it has the form of a sphere. Only the upper hemisphere (= Procrustes pre-shape space) of the shape manifold is shown here with an equilateral triangle chosen arbitrarily to occupy the pole position. Circles centered on the pole represent lines of latitude spaced 18° apart. The lower hemisphere is occupied by identical triangular shapes whose apices fall below the baseline. The shape spaces' equator is occupied by the set of colinear triangles. (Redrawn from an original by F. J. Rohlf)

thereof), all but the three congruent triangles in each shape group exhibit unique coordinate locations in the PCA-decomposed Procrustes shape-coordinate space. These unique locations reflect and summarize their unique shapes.

Note also that the equilateral triangles in this series (triangles 3, 5, and 7 in the gray group) plot at the origin of the PC-1 vs. PC-2 coordinate system (Fig. 3c, left) and at the unit coordinate along PC-3. This is the pole position of a unit hemisphere, the surface of which contains all the other triangles – and all conceivable triangles – arrayed in a systematic manner that reflects their intrinsic and geometrically organized shape differences accurately. All triangular configurations of landmark points are located on the surface of this hemisphere because differences in their sizes (along with any differences in position and orientation) have been discarded during the Procrustes alignment procedure.

This simple mathematical experiment illustrates Kendall's (1984) conclusion that all polygonal shapes exist on the surfaces of hyperdimensional mathematical manifolds of dimension $2k-3$ (where k is the number of polygon vertices) and in which the radius of the manifold reflects the size of the vertex-defined polygon. In the case of triangles (which are the simplest geometric objects that have a shape), this manifold is a sphere.

As can be seen in Fig. 4, all conceivable triangles (including colinear triangles) whose sizes have been adjusted to a unit value can be located on the surface of the three-dimensional triangle shape sphere. The two hemispheres of this sphere separated by the “equator” of colinear triangles contain sets of triangles that are mirror images of each other with the apex vertex reflected across the basal chord. During Procrustes alignment, all three corresponding vertices are rotated to corresponding positions, which reduces the full triangle shape sphere to a Procrustes-aligned shape hemisphere.

Analogous shape manifolds can be constructed for any collection of objects whose forms can be represented, or approximated, by sets of topologically corresponding landmark locations. These manifolds represent precise mathematical realizations of the more ambiguous particle shape spaces created by Wentworth (1922), Zingg (1935), and Sneed and Folk (1958). Such shape spaces can be used either for describing and categorizing the shapes of objects or testing hypotheses concerning the shape similarities or differences between objects and groups (Fig. 5). If care is taken to match topologically corresponding points located either on, or internal to, the outlines of objects, these geometric methods can be extended to the consideration of any polygon-defined shape in either two or three dimensions.

Shape, Fig. 5 Cross sections through the Procrustes shape hemisphere (= Kendall's pre-shape space) illustrating various spatial relations between the reference (gray) and target (white) landmark-defined shapes. (a). Between any two configurations, the Procrustes distance (D) is the length of the shortest arc between the configuration's points on the shape manifold's surface. The partial Procrustes distance (D_p) is the linear distance between these points. For point comparisons for which the arc angle (θ) is small, D_p will provide a good estimate of D . Interestingly, a closer match between the target and reference configuration's points can often be found by relaxing the constraint of size similarity. The full Procrustes distance (D_f) is the minimal distance between the reference and the target configurations when the configuration size of the target is allowed to vary, but not its shape. (b). The distribution of a shape or series of shapes with respect to a reference shape may be portrayed in the

linear spaces that have become traditional in pre-geometric morphometrics by orthogonally projecting their positions on the Procrustes shape manifold to a linear plane. This operation can be accomplished via covariance-based PCA of the complete set of partial warp scores (= relative warps analysis) or direct covariance-based PCA of the Procrustes shape coordinates expressed as deviations from the reference shape. Under this convention the projection plane will be tangent to the shape manifold at the point of the reference shape and exhibit a reduced dimensionality from that of the shape manifold's surface. If the total range of shape variation present within the sample is small, the apparent Procrustes distances ($\hat{D}_p$) between point locations in this tangent space will be good estimates of both the partial Procrustes distance (D_p) and (by extension) the Procrustes distance (D).

Conclusion

The existence of two distinct traditions of shape characterization and analysis in the earth sciences presents challenges to communication across this highly interdisciplinary field. Many of the mathematical formalisms and data analysis methods that are currently applied to biological/paleontological shapes can also be applied successfully to non-biological shapes, often to the advantage of hypothesis tests (e.g., avoidance of the problems associated with the calculation of ratios, reduction in geometric ambiguity). In many practical cases, though, a high degree of geometric fidelity and mathematical sophistication is not necessary in order to characterize a sample of shapes or test a shape-related hypothesis. Moreover, newly available machine-learning approaches to generalized object analysis seem certain to add a new set of options for the analysis of shapes in an earth-science context. While no generalized advice can be offered regarding an approach to pursue in any particular case, familiarity with both the concepts and methods of particle analysis and geometric morphometrics (in addition to machine learning) will ensure access to the greatest possible range of shape-related concepts and shape analysis tools.

Signal Analysis

Signal analysis is an essential and important step for all earth sciences including geophysics; its main aim is to process and interpret all types of registered signals in order to carry out all possible required information (Dimri 2005). Therefore, its usefulness can be judged by its success in extracting maximum useful information for a given signal, which is generally disturbed by different noises (Li et al. 2018); the reliability of the obtained results is strongly dependent on the electronic measurement devices and computational process. This chapter is dedicated to overview the signal analysis steps applied in earth sciences, with some focus on geophysical applications (Herrera et al. 2013).

The Signal

A signal is a term that is applied for any physical representation of information in different forms including mathematical functions, which are related to the inputs of a given system to its outputs. The mathematical description of a signal s provides the possibility to represent, analyze, and treat the information by using mathematical technique sets in the so-called processing systems (Robinson 1981). For example, in geophysics, the signal can represent the information obtained from the response of the geological layers when submitting an artificial energy signal through the earth (Dimri 2005). The interpretation of these seismic signals allows us to construct an image on the different structures of the subsurface (Liu et al. 2016).

The Noise

Any kind of signals that is disturbing the registration, transmission, or interpretation of the main signal is considered to be a noise N . Since the noise is also a type of signal, the concepts of signal and noise are relative to what interest the interpreters in the first place (Li et al. 2018). For example, in astronomy the signal coming from satellites is considered to be noise, and the main signal is the one received from astrophysical resources (i.e., the sun), while for telecommunications, the satellite

signals are the targets. In geophysics, the signals coming from the subsurface are considered to be the main target, while other signals from surface are seen as noise (Li et al. 2018).

The Signal to Noise Ratio (s/N)

This ratio is conventionally used to measure the importance of the noise in comparison to the main signal; it gives a direct indication on how the signal is noised (Wang et al. 2012). If this ratio is close to 1, it means the signal is very noisy and an important part of the signal is overlapped in time with the noise (Li et al. 2018). It is practically calculated by dividing the power of the signal (P_s) by the power of the noise (P_N), and it is often expressed in decibels (dB) as demonstrated by Eq. (1)

$$\left(\frac{S}{N}\right)_{dB} = 10 \log\left(\frac{P_s}{P_N}\right) \quad (1)$$

Signal Classification

The signals are classified according to their properties into different classes, where the most important characteristic of the signal is its evolution as a function of time. Based on that, there are two types of signals.

Deterministic Signals

The evolution of such type of signals over time can be modeled by well-defined mathematical functions; in this type of signal, many classes can be found such as periodic signals, transient signals, and pseudo-random signals.

Random Signals

These signals are characterized by the property that their temporal behavior is unpredictable; therefore, it is necessary to appeal to their statistical properties to describe them. If their statistical properties are invariant in time, they are said to be stationary.

Other Classification

Other classifications of the signals are based on the nature of their variables; continuous signals are distinguished from discrete signals by the nature of the time variable as well as those whose amplitude is discrete or continuous as detailed in Table 1.

Based on Table 1, the signals can be therefore classified into four main types:

- Type 1 (analog signals): their amplitude and time are both continuous.
- Type 2 (quantized signals): its amplitude is discrete while the time is continuous.
- Type 3 (sampled signals): its amplitude is continuous while its time is discrete.
- Type 4 (digital signals): both its amplitude and time are discrete.

Since the seismic signals are analyzed using black box software, they are all digitalized in both amplitude and time; thus, they are all type 4 (Liu et al. 2016). Nevertheless, other types can be also obtained with some predefined requirements.

Signal Analysis, Table 1 Classification of signals based on the nature of its variable and amplitude

		Amplitude	
		Continuous	Discrete
Time	Continuous		
	Discrete		

Important Functions for Signal Analysis

In order to proceed to signal analysis, it is necessary to define some reference signals that will be used later to simplify the mathematical calculations of other techniques for domain transformation. The main signals to ensure are the following.

Sign Function

The sign function is mathematically defined by Eq. (2), and its graphical presentation is given by Fig. 1a. It is conventionally admitted that the value at the origin is $\text{sgn}(t = 0) = 0$.

$$\text{sgn}(t) = \begin{cases} -1 & \text{for } t < 0 \\ +1 & \text{for } t > 0 \end{cases} \quad (2)$$

Step Function

The step function is mathematically defined by Eq. (3) and graphically represented by Fig. 2b. It is conventionally admitted that $u(t = 0) = 1/2$. In some literature, the value given at the origin is 1.

$$u(t) = \begin{cases} 0 & \text{for } t < 0 \\ 1 & \text{for } t > 0 \end{cases} \quad (3)$$

Ramp Function

The ramp function is mathematically defined by Eq. (4) and graphically represented by Fig. 2c.

$$r(t) = t \cdot u(t) = \int_{-\infty}^t u(\tau) d\tau \quad (4)$$

Rectangular Function

The rectangular function is mathematically defined by Eq. (5) and graphically represented by Fig. 2d. It is also called the window function because it serves as a basic windowing function.

$$\text{rect}\left(\frac{t}{T}\right) = \begin{cases} 1 & \text{for } \left|\frac{t}{T}\right| < \frac{1}{2} \\ 0 & \text{for } \left|\frac{t}{T}\right| > \frac{1}{2} \end{cases} \quad (5)$$

Dirac Pulse Function

The Dirac function can be seen as a rectangular function with a width T that tends towards 0 and whose area is equal to 1. It is mathematically defined by Eq. (6) and graphically schematized by Fig. 2e.

$$\delta(t) = \begin{cases} \infty & \text{for } t = 0 \\ 0 & \text{for } t \neq 0 \end{cases} \quad (6)$$

Figure 2e shows the schema of the function but does not represent it because it contains an infinite term; the arrow in this figure indicates the function whose surface should be equal to 1. It should also be noticed that the Dirac function is the derivative of the step function $\delta(t) = \frac{du(t)}{dt}$. The importance of this function is that it is used to sample other complex signals; the passage from one state to another in a given signal is seen as a pulse (Dirac function) if the rise time is very negligible in comparison to the original signal global time (Wang et al. 2012).

Dirac Comb Function

The Dirac comb function is a periodic succession of Dirac impulses, its mathematical presentation is given by Eq. (7), and its graphically appearance is highlighted in Fig. 1f.

$$\delta_T(t) = \sum_{k=-\infty}^{+\infty} \delta(t - kT) \quad (7)$$

T is the period of the comb. This sequence is sometimes referred to as a pulse train or a sampling function because this type of signals is mainly used in sampling.

Cardinal Sinus Function

This function plays an important role in the signal analysis due to its mathematical properties; it is defined mathematically by Eq. (8) and highlighted graphically by Fig. 1g

$$\text{sinc}(t) = \frac{\sin(\pi t)}{\pi t} \quad (8)$$

One of the main important properties of the cardinal sinus function is expressed by

$$\int_{-\infty}^{+\infty} \text{sinc}(t) dt = 1, \quad \int_{-\infty}^{+\infty} \text{sinc}^2(t) dt = 1$$

Frequency Representation

The signals are generally presented as a function of time because our perception of physical world is based on taking the time as the most important variable for all phenomena. However, in many cases this presentation cannot provide deep analysis especially for semi-periodic and quasiperiodic complex phenomenon in time (Benedetto 2010). Therefore, the necessity to transfer these signals into other domains rather than time became primordial. The knowledge of the spectral properties of a signal from its energy is essential (Huang et al. 2015). Thus, the frequency representation of the signal in the frequency domain can be very efficient for energy-phenomenon characterization. This transformation

Signal Analysis, Fig. 1 Most important functions for signal analysis: (a) sign function, (b) step function, (c) ramp function, (d) rectangular function, (e) Dirac pulse function, (f) Dirac comb function, (g) cardinal sinus function, (h) window function for band-pass filter

of a signal from time domain to the frequency domain has many advantages, i.e., it can help in filtering the noise from original signal since the noise is generally characterized by high-frequency dynamics in seismic data (Liu et al. 2016). The Fourier series have been firstly proposed in order to decompose the perfectly periodic signals into sinusoids so that passage can be easily (Chakraborty and Okaya 1995). Later on, the Fourier transform has been introduced as the generalization of Fourier series for all nonperiodic functions.

Fourier Series

The Fourier series principle is based on decomposing the periodic signal into a sum of sinusoids. Thus, it permits to transform easily from time domain to the frequency domain but with the necessary condition that the decomposed signal should have bounded variations. Let's consider the periodic bounded signal $s(t)$; its Fourier series can be written as:

Signal Analysis, Fig. 2 Examples of seismic data analysis: (a) original seismic trace responses of earth, (b) comparison between original and noise traces, (c) one trace extracted from a, (d) one trace extracted from noise data, (e) comparison between original and noised wavelet,

(f) Fourier transform of the wavelet in e, (g) fast Fourier transform of the wavelet in e, (h) example of filtered and stacked wavelet, (i) complete seismic trace

Signal Analysis, Fig. 2 (continued)

Signal Analysis, Fig. 2 (continued)

$$s(t) = S_0 + \sum_{n=1}^{\infty} [A_n \cos(n\omega_0 t) + B_n \sin(n\omega_0 t)] \quad (9)$$

with $\omega_0 = \frac{2\pi}{T_0}$, and $S_0 = \frac{1}{T_0} \int_{(T_0)} s(t) dt$, $A_n = \frac{2}{T_0} \int_{(T_0)} s(t) \cos(n\omega_0 t) dt$, $B_n = \frac{2}{T_0} \int_{(T_0)} s(t) \sin(n\omega_0 t) dt$ is the fundamental pulsation, $n\omega_0$ is the n rank harmonic, and S_0 is the average value of the signal $s(t)$. Other complex presentations of the Fourier series can be found in the literature too. The main limitation of the Fourier series is that it is applied only for periodic functions where the signal variables should be bounded too. For that reason, the Fourier transform is

developed from Fourier series by supposing that all non-periodic functions are periodic functions with a period that tends to infinity as explained in section “[The Fourier Transform](#)”.

The Fourier Transform

The Fourier transform is the generalization of the Fourier series decomposition to all deterministic signals; thus, it provides the spectral presentation of all signals all over the frequency range (Huang et al. 2015). In other terms, it

demonstrates the variation of the amplitude (or energy) of the signal as a function of its frequency. In order to explain that in details, let $s(t)$ be now a deterministic signal; its Fourier transform is a complex function of the frequency, and it is given by Eq. (10).

$$S(f) = FT[s(t)] = \int_{-\infty}^{+\infty} s(t)e^{-j2\pi ft} dt \quad (10)$$

It has been proven that if the transform given by Eq. (10) exists, then the inverse Fourier transform can be obtained by Eq. (11). The modulus of the Fourier transform of a signal is called the spectrum.

$$s(t) = TF^{-1}[S(f)] = \int_{-\infty}^{+\infty} S(f)e^{j2\pi ft} df \quad (11)$$

Table 2 summarizes some of the most useful properties of Fourier transform for signal analysis in earth sciences in general and for seismic processing in particular (Robinson 1981).

Convolution and Deconvolution Principle and the Fourier Transform

The convolution product of a given signal $s(t)$ by another signal $h(t)$ is given by Eq. (12).

$$s(t) * h(t) = \int_{-\infty}^{+\infty} s(k)h(t-k)dk \quad (12)$$

The main utility of the convolution is that it is used to extract the transfer function of systems, since, the output signal of convolution of the input direct impulse function with the transfer function of the system is the transfer function itself; this is called the impulse response of the system. The value of the output signal at time t is thus obtained by summing the past values of the excitation signals, weighted by

system response. It is proven that $TF[a(t) * b(t)] = A(f) \cdot B(f)$.

Filtering Concept

Filtering is a kind of signal analysis, where the frequency spectrum and the phase of the signal are changed based on our need; therefore, the temporal form of the signal is consequently changed (Huang et al. 2015). The changes can be either eliminating (or at least weakening) the unwanted frequencies of the noises or isolating the useful frequencies of the main signal (Li et al. 2018). Thence, an ideal filter can be described by zero attenuation in the frequency band that we want to keep and an infinite attenuation in the band that we want to eliminate. In practice, it is impossible to obtain such a perfect filter, but the best approach is to keep the attenuation lower than a given value A_{max} in the bandwidth and greater than A_{min} in the attenuated band. The bandwidth for filters of seismic data is defined based on regional studies, and they are generally between 20 and 80 Hz (Chakraborty and Okaya 1995). Based on the filter template, which defines the attenuation and the prohibited zones, four types of filters can be constructed: (1) low-pass filter, (2) high-pass filter, (3) band-pass filter, and (4) band-cut filter. By sizing the filter window, only a few analytical functions can be used, which their characteristics can be suitable for the realization of the template. Examples of such functions that will set the physical properties of the filter are Butterworth, Tchebycheff, Bessel, and Cauer.

Modulation Concept

The principle of modulating a signal is mainly used for the signal transmission; it is based on adapting the signal to be transmitted through the transmission channel, wherein modulation of the signal amplitude necessitates a frequency transposition of signal; it is achieved by a simple multiplication, where the necessary bandwidth to transmit a signal of f frequency is $2f$. In order to retrieve the original signal, demodulation process should be involved.

Signal Analysis, Table 2 Properties of the Fourier transform

Domain	$s(t)$	$S(f)$
Linearity	$a \cdot s(t) + b \cdot r(t)$	$a \cdot S(f) + b \cdot R(f)$
Translation	$s(t - t_0)$	$e^{-j2\pi ft_0} S(f)$
	$e^{+j2\pi ft_0} s(t)$	$S(f - f_0)$
Inflection	$s^*(t)$	$S^*(-f)$
Derivation	$\frac{d^n s(t)}{dt^n}$	$(j2\pi f)^n S(f)$
Dilatation	$s(a \cdot t)$ with $a \neq 0$	$\frac{1}{ a } S\left(\frac{f}{a}\right)$
Convolution	$s(t) * r(t)$	$S(f) \cdot R(f)$
	$s(t) \cdot r(t)$	$S(f) * R(f)$
Duality	$S(t)$	$s(-f)$

Digitization

Since the outside world is analog by default, the necessity to analog-to-digital conversion is growing up due the computational limitation of the digital world; the analog conversion to digital is essentially based on three main steps. The first step is the sampling process in order to convert the analog signal into discrete; then the second step is the quantization, which is the association an amplitude value for each time step; and the last step is coding, where each value is associated to its

appropriate code. These steps are gathered in one process named sampling-holding process as detailed in the next subsection.

Sampling-Holding

In practice, the analog to digital conversion is not done instantly; there should be a blocking time of the analog signal for a period of T to have an error-free conversion. The sample-holding is therefore used to achieve this step, where the blocking effect is generally modeled by a window function shifted by a period of $\tau/2$. The mathematical function of sampling and holding process is given by Eq. (13), and its graphical presentation is given by Fig. 1g.

$$\begin{aligned} y(t) &= \sum_{k \rightarrow -\infty}^{+\infty} \text{rect}\left(\frac{t - \frac{\tau}{2} - kT_e}{\tau}\right) \\ &= \text{rect}\left(\frac{t - \frac{\tau}{2}}{\tau}\right) * \sum_{k \rightarrow -\infty}^{+\infty} \delta(t - kT_e) \end{aligned} \quad (13)$$

The process of sampling-and-blocking can therefore be seen as multiplying the signal $s(t)$ by $y(t)$. The Fourier transform of the sampled signal is therefore can be given by Eq. (14).

$$S_e(f) = \frac{\tau}{T_e} \text{sinc}(\tau f) \cdot \sum_{k \rightarrow -\infty}^{+\infty} S(f - kf_e) \cdot e^{-j\pi f \tau} \quad (14)$$

Quantification

The quantization principle consists in adding to any real value x any other value x_q that belongs to a finite set of values according to a certain law: rounding up, rounding up closer, etc. The gap between each value x_q is called no quantization. Rounding off the start value inevitably results in a quantization error called quantization noise (Li et al. 2018).

Coding

Coding consists of associating a composite code with a set of discrete values of binary elements. The most famous codes: natural binary code, shifted binary code, code DCB, and gray code.

FFT: Fast Fourier Transform

In order to be able to apply Fourier Transform with large data, an algorithm is used to obtain the transformation in a much faster time under pre-defined conditions. This algorithm is called the fast Fourier transform. The transformation in discrete domains is given by Eq. (15).

$$X[k] = \sum_{n=0}^{N-1} x[n] \cdot W_N^{nk}, \quad (15)$$

$$\text{with } W_N = e^{-\frac{2j\pi}{N}}, \quad W_N^{2nk} = e^{-\frac{2j\pi nk}{N/2}} = W_{N/2}^{nk}, \quad \text{and } W_N^{nk+N/2} = e^{-\frac{2j\pi(nk+N/2)}{N}} = -W_N^{nk}$$

The necessary condition to use the FFT is that the number of sample should be written as a power of 2: $N = 2^m$; then by separating the odd and the even indices, the repeated calculation operations will be separated as follows: $x_1[n] = x[2n]$ and $x_2[n] = x[2n + 1]$. By exploring this property, we finally find the FFT as given by Eq. (16). The calculation rate will be minimized from N^2 to $N \log_2(N)$.

$$\begin{cases} X[k] = X_1[k] + W_N^k \cdot X_2[k] \\ X\left[k + \frac{N}{2}\right] = X_1[k] - W_N^k \cdot X_2[k] \end{cases} \quad \text{for } 0 \leq k \leq \frac{N}{2} - 1 \quad (16)$$

Example from Geophysics

In the example given in Fig. 2, we will show a seismic signal and some signal analysis techniques that can be applied to it in order to extract the desired information; the signal represents a seismic trace that shows a typical response (reflection) of earth rock to artificially submitted energy signal (Efi and Kumar 1994).

Conclusions

In this chapter, we have briefly reviewed the theory of signal analysis from mathematical perspectives, where definitions and most important functions and their mathematical properties have been given in order to allow beginner students to construct a general idea about this topic. Moreover, examples of signal analysis applications in geophysics have been demonstrated; they will permit future earth scientists in general and geophysicists in particular to link the theoretical information delivered in this chapter with practical applications in their field of study.

Definition

Geophysical signal processing is an important branch of geophysics that deals with various signals and systems. It serves as a backbone for efficient analysis and interpretation of the complex geophysical data. Concepts of signal processing are encountered at various stages, right from the data

acquisition to processing to interpretation. Over the years, geophysical signal analysis techniques have steadily progressed from the use of basic integral transforms to present-day nonlinear signal processing techniques such as wavelet analysis, fractal and multifractal analysis, and empirical mode decomposition technique, which have found their forays in geosciences, paving the way for effectively unravelling the hidden information from the nonlinear and nonstationary geophysical data. The use of these novel signal analysis techniques in geophysical data analysis is always important and essential for a better understanding of the dynamics of the systems that are generating such complex geophysical data.

Introduction

The word “signal” can be best defined as the time or space variation of any physical quantity. While geophysical data constitute time signals (e.g., radiometric data, ionospheric total electron content (TEC) data), and space signals (e.g., well-log data), some are also classed into spatiotemporal signals, which vary as a function of both time and space (e.g., Earth’s magnetic and gravitational field). Also, there are some geophysical signals, which are causal (e.g., seismic data, well-log data, etc.) and noncausal (e.g., Earth’s upper atmospheric data, magnetic field, gravity field, to name a few) (Causal signals are those, which do not occur before the onset of any excitation. Noncausal signals do not require any excitation to occur. They are continuously generated naturally, since time immemorial.). If the statistical properties, such as mean, variance, etc. of a signal, do not vary as a function of space/time, they are defined as stationary signals. Otherwise, they are defined as nonstationary signals. Most geophysical signals are nonstationary in nature and a very few, namely, geomagnetic solar quiet day (Sq) variations, and the TEC data, may be called as quasi-stationary, as they generally exhibit some known periodicity in their temporal behavior. Initially, while the statistical methods helped to understand the behavior of geophysical signals by facilitating to estimate the trends and cyclicities present in the data, the well-known mathematical transforms, such as the Fourier transform and Hilbert transform, to name a few, have found their role in solving the potential field problems, thereby significantly improving the understanding and interpretation of the anomalous in situ geophysical signals. However, since all the above techniques are most effective in analyzing stationary or quasi-stationary signals, they lack in extracting some important information, such as time-frequency localization, from the nonlinear geophysical signals. Before discussing about nonlinearity in the signals, it would be more prudent, if we understand the difference between linearity and nonlinearity in signals, in the first place. If any observational data (y) can

be modeled in the form of, say, $y = mx + c$, where, x is any variable, then that data exhibits linear behavior. On the other hand, if any observational data best fits to a model having exponents, say, $y = x^m$ ($m \neq 1$), then such data exhibits nonlinear behavior. Most observational geophysical data, such as gravity data, magnetic data, seismic and seismological data, well-log data, geomagnetic data, ionospheric data, and weather data, to name a few are all nonlinear in nature. Nonlinear signals exhibit a power-law behavior with time and thus to correctly understand their behavior with time, suitable nonlinear mathematical techniques need to be employed. Basically, the aim is to correctly understand the dynamics of the nonlinear system that is generating such nonlinear signals. For example, the seismological data generated at different places on the Earth are different, which are a result of different subsurface dynamics associated with them (Telesca et al. 2004). Therefore, to correctly understand such nonlinear dynamics of the subsurface, responsible for generating such diverse signals, we must employ nonlinear signal analysis techniques. With the advent of wavelet analysis and other nonlinear and data-adaptive techniques, such as fractal and multifractal analyses and empirical mode decomposition technique, significant improvements have been made in the analysis of geophysical signals.

In this chapter, we first discuss the theory behind the basic integral transforms (mentioned here, as linear signal processing techniques) and their applications in geophysics. We next discuss the theory and geophysical application of continuous and discrete wavelet transform, the fractal and multifractal analysis techniques, and the fully data-adaptive empirical mode decomposition (EMD) technique. Finally, we discuss how the EMD technique facilitates to quantitatively estimate the degree of subsurface heterogeneity, using well-log data of two different wells. For all the above techniques, adequate references are provided for the benefit of the reader to further explore and understand the geophysical applications of all these techniques.

Linear Signal Processing Techniques in Geophysics

In this section, we briefly define the basic integral transforms like the Fourier transform, the Z-transform, and the Hilbert transform and discuss their applications in geophysical signal analysis. Although there are many other integral transforms in the literature, it is not possible to discuss all of them here, and thus we stick only to the well-known above three transforms, which have seen many applications in geophysics.

The Fourier Transform

If a time-varying signal is denoted as $f(t)$, then its Fourier transform, $F(\omega)$, is mathematically expressed as

$$F(\omega) = \int_{-\infty}^{\infty} f(t)e^{-i\omega t} dt \quad (1)$$

Equation (1) explains that the time signal treated with a complex exponential function and summed up over the entire time signal will result in the frequency content of that signal (If the kernel is a negative exponential function in the Fourier transform, it should be positive in the inverse Fourier transform and vice versa.). The greatness of this transformation lies in the fact that the Fourier transform is the only efficient technique that can delineate all the frequencies present in the signal in the entire frequency range $-\infty$ to $+\infty$. $F(\omega)$ is called the power spectrum of $f(t)$. $F(\omega)$ is a complex function, implying that the Fourier transform of a real function will give not only the amplitude spectrum ($|F(\omega)| = A(\omega) = \sqrt{R(\omega)^2 + I(\omega)^2}$) but also the phase spectrum ($\theta(\omega) = \tan^{-1}\left(\frac{I(\omega)}{R(\omega)}\right)$), where $R(\omega)$ and $I(\omega)$, respectively, denote the real and imaginary parts of $F(\omega)$. Accordingly, Eq. (1) can also be written as

$$F(\omega) = |F(\omega)| e^{i\theta(\omega)}$$

By applying a reverse operation, what is known as the inverse Fourier transform, it is also possible to get back the original signal, using the formula

$$f(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\omega)e^{i\omega t} d\omega \quad (2)$$

All types of signals, which satisfy the Dirichlet's conditions (see Hayes 1999), are Fourier transformable. Several properties of the Fourier transform can be found in Haykins (2006). Equation (1) can be applied to a variety of time, space, or spatiotemporal signals in geophysics to determine the parameters of the subsurface anomalous bodies, such as their depth of location, width, etc.

Application of the Fourier Transform to Determine the Subsurface Anomaly Parameters

As an example of the application of the Fourier transform in geophysics, we describe below a methodology to determine the parameters of a horizontal cylinder buried in the subsurface, by analyzing the gravity effect over it, using the Fourier transform. Figure 1 shows the schematic of the horizontal cylinder, having a radius R with depth to the center of the body as h , in the cartesian coordinate system.

Signal Processing in Geosciences, Fig. 1 A schematic representation of the buried horizontal cylinder (see text for the definitions of various parameters).

The gravity anomaly over a horizontal cylinder, as a function of horizontal distance, x , is mathematically expressed as

$$g(x) = \frac{2\pi\gamma\sigma R^2 h}{x^2 + h^2} \quad (3)$$

where γ is the universal gravitational constant, σ refers to the density contrast, and x designates the distance on the surface of the earth along a profile, over which, the gravity measurements are made.

From Eq. (1), the Fourier transform of Eq. (3) is given by

$$G(\omega) = 2\pi\gamma\sigma R^2 h \int_{-\infty}^{\infty} \frac{e^{-i\omega x}}{x^2 + h^2} dx \quad (4)$$

Since the integrand in Eq. (4) has poles at $x = \pm ih$, it needs to be solved using complex integration. Accordingly, considering the path of integration around $x = +ih$, the contour integration of Eq. (4) yields

$$\oint_{-\infty}^{\infty} \frac{e^{-i\omega x}}{x^2 + h^2} dx = \frac{\pi e^{\omega h}}{h} \quad (5)$$

Substituting Eq. (5) in Eq. (4), we get

$$G(\omega) = 2\pi^2 R^2 \gamma \sigma e^{\omega h} \quad (6)$$

Equation (6) at $\omega = 0$ gives

$$G(0) = 2\pi^2 R^2 \gamma \sigma \quad (7)$$

From Eq. (7) we have

$$R = \frac{1}{\pi} \sqrt{G(0)/2\gamma\sigma} \quad (8)$$

Similarly, Eq. (3) at $x = 0$ gives

$$g(0) = \frac{2\pi\gamma\sigma R^2}{h} = \frac{G(0)}{\pi h} \quad (9)$$

Therefore, from Eq. (9), we have

$$h = \frac{G(0)}{\pi g(0)} \quad (10)$$

Equations (8) and (10) explain the role of the Fourier transform in conveniently delineating the subsurface parameters, R and h of the buried anomalous body from its gravity effect. Similar examples of delineating various other parameters of various subsurface anomalous bodies using their respective geophysical anomalous effects can be found in Odegard and Berg (1965), Sharma and Geldart (1968), and Bhimasankaram et al. (1977a, b, 1978).

The Z-Transform

The Z-transform notation of a discrete signal, say, $[y_n] = y_0, y_1, y_2, y_3, \dots, y_{n-1}$, sampled at equal time intervals (denoted as subscripts) is generally expressed in the form of a polynomial in z as

$$Y(z) = y_0 + y_1 z + y_2 z^2 + y_3 z^3 + \dots + y_{n-1} z^{n-1} \quad (11)$$

For noncausal signals, Eq. (11) can be written as

$$Y(z) = y_{-n} z^{-n} + y_{-3} z^{-3} + y_{-2} z^{-2} + y_{-1} z^{-1} + y_0 + y_1 z + y_2 z^2 + y_3 z^3 + \dots + y_n z^n \quad (12)$$

where the coefficients of z represent the amplitudes of the signal at different times. Both in Eqs. 11 and 12, the z can be visualized as a unit delay operator. That means, the z operated on the sample at time t is actually the value of the signal after t units of time are elapsed. Accordingly, we can define

$$z[y_n] = y_{n-1}. \text{ Similarly, } z^2[y_n] = y_{n-2}; z^3[y_n] = y_{n-3}, \text{ etc.}$$

Mathematically, the unit delay operator, z , is expressed as $z = e^{i\omega}$. While the magnitude of this unit delay operator and all the powers of z is always 1, graphically, a single unit delay represents the time taken by the signal in completing one circle in the anticlockwise direction in the argand diagram, when ω goes from 0 to 2π . Similarly, a two-unit delay (i.e., z^2 or $e^{2i\omega}$) represents the time taken by the signal in completing the path 0 to 2π twice in the anticlockwise

direction, and a three-unit delay (i.e., z^3 or $e^{3i\omega}$) represents the time taken by the signal in completing the path 0 to 2π thrice in the anticlockwise direction and so on. This way the time-delayed representation of the signal at different delayed times can be truly expressed in z-transform notation, in the form of a polynomial in z .

Relation Between the Fourier Transform and Z-Transform Equation (11) can be written as

$$Y(z) = \sum_{t=0}^{n-1} y_t z^t \quad (13)$$

If we substitute, $z = e^{i\omega}$ in the above equation, we get

$$Y(\omega) = \sum_{t=0}^{n-1} y_t e^{i\omega t} \quad (14)$$

The analog form of Eq. (14) with extended limits, written as

$$Y(\omega) = \int_{-\infty}^{\infty} y(t) e^{i\omega t} dt \quad (15)$$

defines the Fourier transform.

An interesting question that arises as a consequence is: If the simple process of attaching powers of z to the discrete time signal defines the Z-transform, then the inverse Z-transform should amount to determining the coefficients of z . Let's look into this.

From Eq. (15), the inverse Fourier transform is written as

$$y(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} Y(\omega) e^{-i\omega t} d\omega \quad (16)$$

We know that the integration of $e^{in\omega}$ (or z^n) over the integral $-\pi \leq \omega < \pi$ is nonzero for $n = 0$ and is equal to 0 for all $n \neq 0$ i.e.

$$\begin{aligned} \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{in\omega} d\omega &= \frac{1}{2\pi} \int_{-\pi}^{\pi} (\cos n\omega + i \sin n\omega) d\omega \\ &= \begin{cases} 1 & \text{for } n=0 \\ 0 & \text{for } n \neq 0 \end{cases} \end{aligned} \quad (17)$$

Therefore, accordingly, changing the limits of integration and in terms of discretized function, Eq. (16) can be written as

$$\begin{aligned} y(t) &= \frac{1}{2\pi} \int_{-\pi}^{\pi} (\dots + y_{-2} e^{-2i\omega} + y_{-1} e^{-i\omega} + y_0 + y_1 e^{i\omega} \\ &\quad + y_2 e^{2i\omega} + \dots) e^{-i\omega t} d\omega \end{aligned} \quad (18)$$

Invoking the Dirac delta function, the left-hand side of Eq. (18) can be written as

$$y(t) = \sum_l y_l \delta(t-l) \quad (19)$$

Therefore, by virtue of Eq. (17), all terms in Eq. (18) would vanish except the term with the coefficient of z with power zero, actually contributing to the integral. Thus, with the help of Eq. (19), we can write Eq. (18) as

$$y_t = \frac{1}{2\pi} y_t \int_{-\pi}^{\pi} d\omega = y_t \quad (20)$$

This proves that the inverse Z-transform facilitates to identify the coefficients of powers of z .

Z-transform has a lot of applications in designing the digital filters and in determining their stability by calculating the transfer functions and poles and zeros of digital filters (see Hayes 1999; Haykins 2006). Thus, the Z-transform has indirect application in geophysics, in the sense that they will be effectively used in the filtering and windowing operations of geophysical signals.

The Hilbert Transform

We earlier have seen that the Fourier transform operating on a given signal changes the time domain signal to frequency domain, thereby facilitating to determine its frequency content. The Hilbert transform on the other hand, while keeping the time signal in the same time domain, will change its phase content. In other words, Hilbert transform facilitates to characterize the signal based on its phase information.

The Hilbert transform is a linear time-invariant filter, whose transfer function results in changing the phase of each frequency in the input signals by an amount of $\pi/2$ radians. Let us understand the concept of Hilbert transform further.

Let us examine the spectral amplitudes of cosine and sine waves, as shown in Fig. 2. It can be seen from Fig. 2a that the spectral amplitude for cosine wave is symmetric and will appear only on the real plane for both positive and negative frequencies. In contrast, for sine wave (Fig. 2b), the spectral amplitude is asymmetric and will appear only on the imaginary plane for both positive and negative frequencies. Accordingly, the phase is $+90^\circ$ for the positive frequencies

Signal Processing in Geosciences, Fig. 2 Schematic representation of spectral amplitudes of (a) cosine and (b) sine waves and (c) and their rotational transformation. “A” designates the amplitude of cosine and sine waves

and -90° for the negative frequencies. From Fig. 2c, we can easily observe that if we rotate the negative frequency components of the cosine by $+90^\circ$ and the positive frequency components by -90° , we can transform a cosine function into a sine function. This rotational transformation is called Hilbert transformation. In other words, the Hilbert transform operation involves rotation of all negative frequency components of a signal by a $+90^\circ$ phase shift and all positive frequency components by a -90° phase shift (see Fig. 2c). Thus, it is equivalent to multiplying the negative phasor by $+i$ and the positive phasor by $-i$ in the frequency domain. It is important to note here that the Hilbert transform affects only the phase of the signal and has no effect on the amplitude.

If $g(t)$ is a real-valued time signal and $\hat{g}(f)$ denotes its Hilbert transform in the frequency domain, then $\hat{g}(f)$ is defined as

$$\hat{g}(f) = \begin{cases} -i g(f) & f > 0 \\ +i g(f) & f < 0 \end{cases} \quad (21)$$

Equation (21) implies that, while the Hilbert transform of a cosine function results in a sine function, the Hilbert transform of a sine function yields a negative cosine function. A close observation of Eq. (21) explains that it can be written as

$$\hat{g}(f) = -i \operatorname{sgn}(f) g(f) \quad (22)$$

where, $\operatorname{sgn}(f)$ denotes the signum function. Equation (22) defines the frequency domain representation of the Hilbert transform, representing the multiplication of two functions, namely, $-i \operatorname{sgn}(f)$ and $g(f)$. Therefore, according to the convolution theorem, Eq. (22) transforms to convolution of respective time functions in the time domain, given as (Convolution theorem states that the convolution of two functions in time domain is equal to multiplication of their respective Fourier spectra in frequency domain)

$$\hat{g}(t) = \frac{1}{\pi t} * g(t) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{g(\tau)}{t - \tau} d\tau \quad (23)$$

where $1/\pi t$ defines the inverse Fourier transform of the function $-i \operatorname{sgn}(f)$. Eq. (23) represents the time domain form of Hilbert transform. The Hilbert transform has a lot of applications in geophysics, particularly in solving the potential field problems involving delineation of subsurface anomaly parameters from the measured gravity or magnetic field in any area (Mohan et al. 1982; Sundararajan 1983; Sundararajan and Srinivas 2010).

Another Definition of Hilbert Transform

From Equation (1), we can have

$$F(\omega) = R(\omega) - iI(\omega) \quad \text{and} \quad F(-\omega) = R(\omega) + iI(\omega)$$

$$\begin{aligned} \text{where, } R(\omega) &= \int_{-\infty}^{\infty} f(t) \cos \omega t dt \quad \text{and} \quad I(\omega) \\ &= \int_{-\infty}^{\infty} f(t) \sin \omega t dt \end{aligned}$$

Therefore, $R(\omega)$ and $I(\omega)$ can be written as

$$R(\omega) = \frac{F(\omega) + F(-\omega)}{2} \quad \text{and} \quad I(\omega) = i \left(\frac{F(\omega) - F(-\omega)}{2} \right)$$

Equation (2) can be written as

$$f(t) = \frac{1}{2\pi} \int_{-\infty}^0 F(\omega) e^{i\omega t} d\omega + \int_0^{\infty} F(\omega) e^{i\omega t} d\omega$$

Put $\omega = -\omega$ in the first integral; we have

$$f(t) = \frac{1}{2\pi} \int_0^{\infty} F(-\omega) e^{-i\omega t} d\omega + \int_0^{\infty} F(\omega) e^{i\omega t} d\omega$$

Using the above relations for $R(\omega)$ and $I(\omega)$, the above equation can be written as

$$f(t) = \frac{1}{\pi} \int_0^{\infty} R(\omega) \cos \omega t + I(\omega) \sin \omega t d\omega \quad (24)$$

From the above definition, Hilbert transform of Eq. 24 can be written as

$$\hat{f}(t) = \frac{1}{\pi} \int_0^{\infty} R(\omega) \sin \omega t - I(\omega) \cos \omega t d\omega \quad (25)$$

Equation (25) is another definition of Hilbert transform, which is widely used in the Hilbert analysis of geophysical signals.

Determination of Subsurface Anomaly Parameters from Gravity Field Using Hilbert Transform

Let us consider the mathematical expression for the gravity anomaly over a horizontal cylinder, as a function of horizontal distance, x , which is given in Eq. (3), whose Fourier transform is given in Eq. (6). We find that $R(\omega) = 2\pi^2 R^2 \gamma \sigma e^{\omega h}$ and $I(\omega) = 0$ in Eq. (6). Using Eq. (25), the Hilbert transform of Eq. (3) is given by

$$\hat{g}(x) = \frac{1}{\pi} \int_0^{\infty} R(\omega) \sin \omega x - I(\omega) \cos \omega x d\omega \quad (26)$$

Substituting $R(\omega)$ and $I(\omega)$ in Eq. (26), we have

$$\hat{g}(x) = 2\pi R^2 \gamma \sigma \int_0^{\infty} e^{\omega h} \sin \omega x d\omega \quad (27)$$

From standard integrals, the solution to Eq. (27) is given by

$$\hat{g}(x) = \frac{2\pi R^2 \gamma \sigma x}{x^2 + h^2} \quad (28)$$

If we plot $g(x)$ and $\hat{g}(x)$ as function of x , then at the point of intersection, say, x_1 , we have $g(x_1) = \hat{g}(x_1)$. Accordingly, we have

$$\begin{aligned} \frac{2\pi \gamma \sigma R^2 h}{x_1^2 + h^2} &= \frac{2\pi R^2 \gamma \sigma x_1}{x_1^2 + h^2} \\ \Rightarrow x_1 &= h \end{aligned} \quad (29)$$

This indicates that the depth to the center of the horizontal cylinder is simply the distance, x_1 , from the origin in the $g(x)$ and $\hat{g}(x)$ plot. Secondly, at the origin, we have

$$\begin{aligned} \hat{g}(0) &= 0; g(0) = \frac{2\pi \gamma \sigma R^2}{h} = \frac{2\pi \gamma \sigma R^2}{x_1} \\ \Rightarrow R &= \sqrt{\frac{g(0)x_1}{2\pi \gamma \sigma}} \end{aligned} \quad (30)$$

Thus, the subsurface anomaly parameters, R and h of the horizontal cylinder (Fig. 1) could be easily derived from the Hilbert transform. Similarly, several other examples of the application of Hilbert transform to analyze geophysical signals can be found in Mohan et al. (1982), Sundararajan (1983), and Sundararajan and Srinivas (2010).

Derivation of Time Domain Representation of the Hilbert Transform from the Fourier Transform

Substituting $R(\omega)$ and $I(\omega)$ (see section “Another Definition of Hilbert Transform”) in Equation (25), we get

$$\begin{aligned} \hat{f}(t) &= \frac{1}{\pi} \int_0^{\infty} \left(\int_{-\infty}^{\infty} f(\tau) \cos \omega \tau d\tau \right) \sin \omega t \\ &\quad - \left(\int_{-\infty}^{\infty} f(\tau) \sin \omega \tau d\tau \right) \cos \omega t d\omega \end{aligned} \quad (31)$$

$$= \hat{f}(t) = \frac{1}{\pi} \int_0^{\infty} \int_{-\infty}^{\infty} f(\tau) (\sin \omega(t - \tau)) d\tau d\omega \quad (32)$$

Regrouping the terms and interchanging the order of integration, we have

$$= \hat{f}(t) = \frac{1}{\pi} \int_{-\infty}^{\infty} f(\tau) d\tau \int_0^{\infty} (\sin \omega(t - \tau)) d\omega \quad (33)$$

From standard integrals, we know that

$$\int_0^{\infty} \sin \omega(t - \tau) d\omega = \frac{1}{t - \tau} \quad (34)$$

Substituting Eq. (34) in Eq. (33), we get

$$\hat{f}(t) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{f(\tau)}{t - \tau} d\tau \quad (35)$$

Note the similarity of Eqs. 23 and 35. Thus Eq. (35) could also be seen as the relation between the Fourier transform and the Hilbert transform.

Role of Nonlinear Signal Processing Techniques in Geophysics

The mathematical transformations that we discussed so far are linear signal analysis techniques. However, since most geophysical data are nonlinear and nonstationary in nature, analyzing them with nonlinear signal analysis techniques will be more appropriate. In this section, we discuss about the role of some nonlinear signal analysis techniques, such as wavelet analysis and nonlinear data-adaptive techniques such as fractal and multifractal analyses and empirical mode decomposition technique.

Wavelet Analysis

The conventional signal analysis technique, Fourier transform, can only provide information about the frequencies and their respective phases present in the signal under investigation. While this is fine, we cannot infer the time variation of frequencies present in the signal with the Fourier transform. In other words, with the Fourier transform, it is impossible to find out, when in time, the frequencies of our interest are occurring in the signal? This is largely due to the limitation of the Fourier transform, as it has cosine and sine functions as the basis functions, which are infinitely supported and cannot be defined in the $\mathcal{L}^2(\mathbb{R})$ domain. As a result, the time localization of frequency components is not possible in Fourier domain. But, why such an information is important in the first place? It is because the frequency variations in the nonlinear signals (rapid or slow) occurring at irregular times manifest the dynamical behavior of the system as a function of time. Therefore, knowledge about the time localization of frequency components is always important for better understanding and characterization of the dynamics of the system generating such nonlinear signals. Therefore, to extract such useful information from nonlinear signals, we need to employ suitable mathematical techniques in their analysis.

Wavelet analysis is one such technique, which provides such vital information. Wavelet analysis facilitates to detect the time-varying frequency components in nonlinear and

nonstationary signals with required resolution. In other words, if some frequencies of interest occur at irregular times in nonlinear signals, the use of wavelet analysis is ideally suited to detect their temporal behavior. This also facilitates to treat noises in the data as independent entities for their easy identification and processing, thereby enhancing the signal-to-noise ratio in the data.

A simple understanding about how wavelets help in the effective characterization of the signal can be seen as follows:

- From a time domain signal, the time information can be easily obtained but not the frequency information (Fig. 3a). Hence, the time localization is easy in time domain signals.
- Similarly, from the frequency spectrum, the frequency information can be easily obtained but not the time information (Fig. 3b). Hence, the frequency localization is easy to obtain from the frequency spectra.
- If we apply a moving window of fixed length to any signal and compute the Fourier transform of it within that window at every location of its movement, then we get, what is known as the short-time Fourier transform (STFT) or windowed Fourier transform (Gabor 1946) of that signal. In STFT, the idea is to break up the signal into smaller portions with a fixed window length and Fourier analyze each portion of the signal to determine its frequency content. Mathematical representation of the STFT of a time function $f(t)$ and a window function $g(t)$ is given by (Gabor 1946)

$$\text{STFT}(\tau, s) = \int_{-\infty}^{\infty} f(t)g(t-\tau)e^{-i2\pi st} dt$$

In STFT, although the short lengths of data are considered at each step, the main transformation again is FT, whose basis functions, as mentioned above, are again the infinitely supported sine and cosine functions and thus the problem of time-frequency localization with good resolution still persists.

Signal Processing in Geosciences, Fig. 3 Schematic representation of comparison of signals in (a) time domain, (b) Fourier domain, (c) Short-time Fourier transform (STFT) domain, and (d) wavelet domain

Furthermore, because the window length is fixed at each step, the STFT partitions the entire time-frequency plane with cells of equal size and thus similar time-frequency resolution is obtained, as shown in Fig. 3c (see Graps 1995; Mallat 1999).

Since a fixed window length needs to be used in STFT to analyze the entire signal to estimate all the frequencies present in it, the resolution of the frequencies is the same at all locations in the time-frequency plane, which may not be the desired resolution most of the times. This is one of the shortcomings of STFT technique. Further, the Fourier transformation is not ideally suited for analyzing short lengths of data (Burg 1975).

- However, in the case of wavelet analysis, the higher frequencies (smaller scales) are well localized in time, but their frequency localization is poor. On the other hand, the lower frequencies (larger scales) have a very good frequency localization but poor time localization. This can be better visualized in Fig. 3d.

This explains that the wavelet analysis facilitates to visualize the data at different frequency resolutions. If we analyze the signals with larger (smaller) scales of the wavelet function, we get a good resolution of the low (high) frequencies present in the data. Wavelet analysis involves use of a wavelet function, called analyzing wavelet or “mother wavelet”. The chosen mother wavelet is treated with a signal as an inner product in translated (shifted in time) and dilated (compressed or expanded) fashion to determine the time-frequency localization in the data.

It is important to note the following basic difference between the Fourier transform and wavelet transform. In the Fourier transform of a nonlinear signal, the Fourier coefficients of the transformed signal represent the contribution of respective sine and cosine function at each frequency, as the sine and cosine functions are the basis functions for the Fourier transform. In contrast, in the case of wavelet transform, the mother wavelet function itself is the basis function, which is compressed and dilated, while analyzing the signal at different time locations of the signal, thereby facilitating to extract the presence of high and low frequencies in the signal respectively, with good resolution. For example, to identify the sharp discontinuities or spikes or singularities present in the signal, the wavelet function at smaller scales (i.e., in the compressed form) could be used, and to identify the low-frequency features present in the signal, larger scales of the same wavelet function (i.e., in the dilated form) could be used. The scale and frequency are inversely related. Since the mother wavelet is the basis function in wavelet transform and since many wavelets can be defined and used to analyze a variety of nonlinear signals, the wavelet transform has many basis functions.

Basic Theory of Wavelet Transform

A wavelet is a small wave having a finite length in time (in technical terms known as *compactly supported*) and represented as a real or complex-valued function, say, $\psi(t)$, satisfying the following conditions:

$$\int \psi(t) dt = 0 \quad (36)$$

$$\int \psi^2(t) dt = 1 \quad (37)$$

Equation (36), known as *admissibility condition*, implies that the average value of the wavelet function in the time domain must be zero and that the function $\psi(t)$ must be oscillatory (so that the sum of its positive and negative excursions is zero). Eq. (37), known as *regularity condition*, implies that $\psi(t)$ must be finite in length and have finite energy. In other words, this condition signifies the fast decay of the wavelet. Further details about these two conditions can be found in Daubechies (1992) and Burrus et al. (1998).

The wavelet function, $\psi(t)$, signifying the time-frequency localization is defined as

$$\psi_{(\tau,s)}(t) = \frac{1}{\sqrt{s}} \psi\left(\frac{t-\tau}{s}\right) \quad (38)$$

where $s > 0$ indicates the scale (or dilation parameter) and τ indicates the translation parameter. s is analogous to frequency, in the sense that larger scales (low frequencies) provide overall information of the signal and smaller scales (high frequencies) provide detailed information of the signal. The scale-frequency relation is given by $f = \frac{f_c}{s\Delta t}$, where f_c indicates the central frequency of the wavelet and Δt refers to the sampling interval and f indicates the pseudo frequency of the wavelet corresponding to the scale, s . τ refers to the time location of the wavelet window as it is slid over the signal along the time axis of the signal and thus apparently refers to time information in the transformed domain.

If two functions $f(t)$ and $g(t)$ are square integrable in $\mathbb{R}$ (i.e., $f(t), g(t) \in \mathcal{L}^2(\mathbb{R})$), then their inner product is defined as

$$\langle f(t)g(t) \rangle = \int_{\mathbb{R}} f(t) \cdot g^*(t) dt \quad (39)$$

where “*” indicates the complex conjugate. According to (39), the wavelet transform of a function $f(t)$ can be defined as the inner product of the mother wavelet $\psi(t)$ and $f(t)$, given by

$$\text{WTf}(\tau, s) = \frac{1}{\sqrt{s}} \int f(t) \cdot \psi\left(\frac{t-\tau}{s}\right) dt \quad (40)$$

Equation (40) explains that the wavelet transformation gives a measure of the similarity between the signal and the

wavelet function. Such a measure at any particular scale s_0 and translation τ_0 is identified by a wavelet coefficient. The larger the value of this coefficient, the higher the similarity between the signal and the wavelet at τ_0, s_0 and vice versa. If a large number of high wavelet coefficients occur by using a particular wavelet, then that indicates the higher degree of suitability of that wavelet to study the signal under investigation.

Two types of wavelet transforms are continuous wavelet transform (CWT) and discrete wavelet transform (DWT). A brief explanation of both these techniques is provided below.

The Continuous Wavelet Transform (CWT)

In CWT (Eq. 40), the inner product of the signal and the wavelet function is computed for different segments of the data by continuously varying τ and s . Because the wavelet window can be scaled (compressed or dilated) at different levels of analysis, the time localization of high-frequency components of the signal and frequency localization of low-frequency components of the signal can be effectively achieved. Because the wavelet is translated along the time axis of the signal in a continuous fashion, the CWT is ideally suited to identify the jumps and singularities present in the data (Jaffard 1991). In CWT, the wavelet window is first placed at the beginning of the signal. The inner product of the signal and wavelet is computed, and the CWT coefficients are estimated. Next, the wavelet is slightly shifted along the time axis of the signal, and the CWT coefficients are again computed. This process is repeated till the end of the signal is reached. Figure 4a depicts the pictorial representation of the above operation. Next, the wavelet window is dilated (or increased in scale by stretching) by a small amount, and the above process is repeated at that scale, at all translations. Likewise, the CWT coefficients are calculated for several scales and translations. Finally, all the CWT coefficients corresponding to all translations and dilations are expressed in the form of a contour plot in the time-scale plane, known as the *scalogram*. Figure 4b depicts an example of a scalogram, obtained by performing wavelet analysis of gamma ray log data using the Gaus1 wavelet (see Chandrasekhar and Rao 2012). It can be seen in Fig. 4b that the CWT can clearly delineate and distinguish the thin and thick interfaces between different lithologies (seen as alternating sequences of low and high wavelet coefficients) at small and high wavelet scales as a function of depth, representing the high and low frequency features present in the data respectively.

According to Eq. (40), the scalogram signifies that any given one-dimensional time signal is transformed into a two-dimensional time-scale (read as time-frequency) plane, thereby increasing the degrees of freedom to understand the given signal effectively. Thus, the wavelet scalograms facilitate to identify what frequencies are present at what times in

any given timeseries. CWT has been applied to a variety of problems in various branches of science and engineering, such as geophysical fluid dynamics (Farge 1992; Farge et al. 1996), geomagnetism (Alexandrescu et al. 1995; Kunagu et al. 2013; Chandrasekhar et al. 2013, 2015), material science (Gururajan et al. 2013), and electromagnetic induction studies (Zhang and Paulson 1997; Zhang et al. 1997; Garcia and Jones 2008). In the case of well-logging, the wavelet analysis has found its wide applications in effectively describing the inter-well relationship (Jansen and Kelkar 1997), determining the sedimentary cycles (Prokoph and Agterberg 2000), reservoir characterization (Panda et al. 2000; Vega 2003), and the space localization and the depths to the tops of reservoir zones (Chandrasekhar and Rao 2012 and references therein; Hill and Uvarova 2018, Zhang et al. 2018). Chandrasekhar and Rao (2012) have also explained the optimization of suitable mother wavelets through histogram analysis of CWT coefficients.

Translation-Invariance Property of Wavelets in CWT Unlike in the Fourier transform, one of the important properties of wavelets in CWT is their translation-invariance property. It explains that a small amount of shift in the wavelet function will also result in the same amount of shift in the wavelet transformed signal. Mathematically, this can be proved as follows.

Let $f_{t_0} = f(t - t_0)$ be the time-shifted form of the signal $f(t)$, by a small shift, t_0 . The CWT of f_{t_0} is given by

$$\text{CWT}f_{t_0}(\tau, s) = \frac{1}{\sqrt{s}} \int f(t - t_0) \cdot \psi\left(\frac{t - \tau}{s}\right) dt \quad (41)$$

Put $t' = t - t_0$ in (41). Then we have

$$\text{CWT}f_{t_0}(\tau, s) = \frac{1}{\sqrt{s}} \int f(t') \cdot \psi\left(\frac{t' - (\tau - t_0)}{s}\right) dt' \quad (42)$$

$$= \text{CWT}f(\tau - t_0, s) \quad (43)$$

Equation (43) explains that, since the output is also shifted in time by the same amount as in the input, the CWT is translation-invariant. The translation-invariance property plays a vital role in identifying the stable features in shifted images in pattern recognition (Ma and Tang 2001). For various other properties of wavelets, the reader is referred to Mallat (1989, 1999).

Discrete Wavelet Transform (DWT)

In CWT, since the analysis of the entire signal is done by translating and dilating the wavelet in a continuous fashion, the CWT has proven to be very effective in identifying the sudden jumps and singularities in the data (Alexandrescu et al. 1995; Chandrasekhar et al. 2013). Further, in the

Signal Processing in Geosciences, Fig. 4 (a)

A pictorial representation of the CWT operation. First, the CWT coefficients, when the wavelet at translation $\tau = 0$ and dilation $s = 1$, are computed. Next, the coefficients, when the wavelet at translation $\tau = 1$ and dilation $s = 1$, are obtained. Likewise, for the same scale of the wavelet, the coefficients corresponding to all other translations, $C_{2,1}, C_{3,1}, \dots, C_{n,1}$, are obtained. Next, the above steps are repeated for different translations and dilations of the wavelet. Then, a complete scalogram depicting the time-scale representation of the signal under study is obtained (after Chandrasekhar and Dimri 2013). (b) An example of a scalogram obtained by performing CWT on gamma ray log data with Gaus1 wavelet (after Chandrasekhar and Rao 2012). The color scale represents the values of wavelet coefficients in the scalogram

scalogram, the region, where the $WTf(\tau, s)$ is nonzero, is known as the region of support in the τ - s plane. However, such an analysis in continuous fashion also produces a lot of redundant information, and thus the entire support of $WTf(\tau, s)$ may not be required to recover the signal $f(t)$, particularly, when it could be possible to represent any signal with a fewer wavelet coefficients. Therefore, to reduce the redundancy, the discrete wavelet transform (DWT) has been introduced (Daubechies 1988; Mallat 1989). Unlike in CWT, the translation and dilation operations in DWT are done in discrete steps by considering, $s = s_0^k$; $\tau = l\tau_0 s_0^k$, where k and l are integers, known as scale factor and shift factor, respectively. Thus, the DWT representation of Eq. (38) is given by (Daubechies 1988)

$$\psi_{k,l}(\tau, s) = \frac{1}{\sqrt{s_0^k}} \psi\left(\frac{t - l\tau_0 s_0^k}{s_0^k}\right) \quad (44)$$

The translation parameter, $l\tau_0 s_0^k$, depends on the chosen dilation rate of the scale (Daubechies 1988). For all practical purposes, generally, the values for s_0 and τ_0 are chosen as 2 and 1, respectively, so that the dyadic sampling is obtained both on frequency (scale) and time axes. Since the DWT samples both the time and scale in a dyadic fashion, it is not translation-invariant (see Ma and Tang 2001).

The DWT is computed using Mallat's algorithm (Mallat 1989), which essentially consists of successive low-pass and high-pass filtering steps. First, the signal ($X[n]$) to be wavelet

transformed is decomposed into high-frequency ($h[n]$) and low-frequency components ($l[n]$). $h[n]$ and $l[n]$ are also, respectively, known as detailed and approximate coefficients. While the former are known as level 1 coefficients, the latter are again decomposed into the next level of detailed and approximate coefficients and so on. A pictorial representation of the entire DWT process described above is shown in Fig. 5. However, at this stage, it is important to understand what exactly happens at each level of such decomposition.

The successive decomposition of the signal into detailed and approximate coefficients implies that at the first level of decomposition, the frequency resolution of the detailed coefficients is enhanced, thereby reducing its uncertainty by half. The decimation by two (see Fig. 5) halves the time resolution, as the entire signal after the first level of decomposition is represented by only half the number of samples. Therefore, in the second level of decomposition, while the half-band low-pass filtering removes half of the frequencies, the

Signal Processing in Geosciences, Fig. 5 Schematic representation of the DWT operation in the form a tree. The number “2” in the circles indicates the decimation factor for down sampling. See text for more description of this tree (after Chandrasekhar and Dimri 2013)

decimation by two doubles the scale. With this approach, the time resolution in the signal gets improved at high frequencies, and the frequency resolution is improved at low frequencies. Such an iterative process is repeated until the desired levels of resolution in frequency are reached. However, the important point to note here is that at every wavelet operation, only half of the spectrum is covered. Does this mean an infinite number of operations are needed to compute the DWT? The answer is no. The DWT process needs to be carried out up to a reasonable level, when the required time and frequency resolutions are achieved. The scaling function of the wavelet is used to control this. Let's summarize the above description as follows: In DWT, the given signal is analyzed using the combination of a wavelet function (denoted by $\psi(t)$) and a scaling function (denoted by $\phi(t)$). While the wavelet function helps to calculate the detailed coefficients (high frequency components), the scaling function helps to calculate the approximate coefficients (low frequency components). Finally, the DWT of the original signal is obtained by concatenating all the detailed and approximate coefficients. The correctness of the reconstructed signal will suggest, whether the required levels of decomposition in DWT were properly achieved or not. Thus, the DWT can be viewed as a filter bank operation. More details about DWT and design of wavelets can be found in several literatures such as Daubechies (1988, 1992), Mallat (1989, 1999), Sharma et al. (2013), and Sengar et al. (2013), to name a few.

The discretization of translation and dilation parameters in DWT gives rise to a two-dimensional sequence, $d_{j,k}$, commonly referred to as the DWT of the function $f(t)$. In other words, DWT amounts to mapping of $f(t)$; $t \in \mathbb{R}$ into a two-dimensional sequence, $d_{j,k}$. This implies, any signal, $f(t)$, $\in \mathcal{L}^2(\mathbb{R})$ can be represented as an orthogonal wavelet series expansion if the sampling on the τ - s plane is adequate, thereby reducing the redundancy in the estimation of wavelet transform coefficients (Sharma et al. 2013). Because of such a significant reduction in the redundant computations, DWT offers a wide range of applications, particularly in field of image processing. In geosciences, it is widely used in the fields of remote sensing and geomorphology. The next section provides a brief account of the application of multiresolution analysis of remote sensing images based on DWT.

Multiresolution Analysis of Remote Sensing Images

Remote sensing is a well-known technique used to classify different regions on the earth, based on the amount of electromagnetic radiation reflected from such regions. Changes in the amount and properties of the electromagnetic radiation in any region are valuable sources of data for interpreting the geological and geophysical properties of the region. The amount of electromagnetic radiation depends on the frequency of operation, instantaneous field of view or spatial resolution, radiometric resolution, etc. Data acquired in the

form of images correspond to localized quantization levels of radiometric resolution in the spectral band of each pixel. Although various techniques have been developed to process and analyze the data (see Gonzalez and Woods 2007), it is difficult to analyze and assess the local changes of the intensity in individual pixels in an image. As discussed earlier, given the poor localization properties of the sinusoid basis functions used in the Fourier transform, the Fourier transform is not very effective in extracting the localized features of the image. To overcome this problem, a multiresolution analysis technique, based on DWT, can be implemented, which can provide a coarse-to-fine and scale-invariant decomposition for the interpretation of images (Mallat 1989).

According to Mallat's algorithm, an input image is analyzed with high-pass and low-pass filters using a wavelet function and its associated scaling function, and down-sampling (Fig. 5). Four images (each one with half the size of the original image) are obtained corresponding to high frequencies in the horizontal direction and low frequencies in the vertical direction (HL), low frequencies in the horizontal direction and high frequencies in the vertical direction (LH), high frequencies in both directions (HH), and low frequencies in both directions (LL). The last image (LL) is a low-pass version of the original image and is called as the approximation image. Figure 6a shows a three-level decomposition where LL1 (approximation sub-band at level 1) is further decomposed into LL2, LH2, HL2, and HH2. This procedure is repeated for the approximation image at each resolution 2^j (for dyadic scales).

Wavelets are viewed as the projection of the signal on a specific set of $\psi(t)$ and $\phi(t)$ functions in the vector space, defined as

$$\psi(t) = \sum_{n \in \mathbb{Z}} h[n] \phi(2^s t - \tau) \quad (45)$$

$$\phi(t) = \sum_{n \in \mathbb{Z}} l[n] \phi(2^s t - \tau) \quad (46)$$

where $h[.]$ are high-pass filter coefficients and $l[.]$ are low-pass filter coefficients of filter bank. s and τ , respectively, denote the scaling and translating indexes.

The signal decomposition into different frequency bands is obtained by successive high-pass and low-pass filtering of the time domain signal. The original signal $X[n]$ is first passed through a half-band high-pass filter $h[n]$ and a low-pass filter $l[n]$. After the filtering, half of the samples can be eliminated according to Nyquist's criteria; the signal can therefore be down-sampled by 2, by eliminating every other sample. This constitutes one level of decomposition and can mathematically be expressed as follows

$$\begin{aligned} o_h[t] &= \sum_n X[n] \cdot h[2t - n] \text{ and } o_l[t] \\ &= \sum_n X[n] \cdot l[2t - n] \end{aligned} \quad (47)$$

where o_h and o_l are the outputs of the high-pass and low-pass filters respectively, after down-sampling by two. Eq. (47) is iteratively repeated to obtain DWT coefficients at other levels of decomposition. Figure 6b shows an image of Kuwait City, acquired by the Indian Resourcesat-1 satellite with a spatial resolution of 5.8 m x 5.8 m (609 x 609 pixels). This resolution is well suited for texture analysis, since a spatial resolution of this order is not adequate to extract individual buildings or narrow roads but groups of them, which render a visible checked pattern in dense urban areas. Figure 6c shows the approximate and detailed sub-bands of the original image, where different horizontal, vertical, and diagonal details of urban features can be visualized.

Several methods, including wavelet, curvelet, and contourlet transforms have been used in multiresolution analysis for image enhancement (Ansari and Buddhiraju 2015), texture analysis (Ansari and Buddhiraju 2016), slum identification (Ansari et al. 2020a), and change detection (Ansari et al. 2020b) applications using remotely sensed images.

Fractal and Multifractal Analyses

Benoit B. Mandelbrot, who invented fractal theory, first coined the term, *fractal*, to open a new discipline of mathematics that deals with non-differentiable curves and geometrical shapes (Mandelbort 1967). The fractal theory provides a framework to study irregular shapes as they exist, instead of approximating them using regular geometry, which usually is done for the sake of mathematical convenience. A prime characteristic of fractal objects is that their measured metric properties, namely, the length, area, or volume, are a function of the scale lengths of measurement. Mandelbrot, in his landmark paper, entitled, "How long is the coast of Britain?" (Mandelbort 1967), illustrates this property by explaining that finer details of coastline are not well realized at larger scale lengths (lower spatial resolution) but become apparent and thus well recognized only at smaller scale lengths (higher spatial resolution). This implies that the measured length of any irregular or wriggled line increases with a decrease in scale length. This further implies that in fractal geometry, the Euclidean concept of "length" becomes a continuously varying process rather than a fixed entity.

Two types of fractals that we largely deal with in nature are classed as "self-similar fractals" and "self-affine fractals." A fractal is defined as self-similar, if its geometry is retained even after magnification. Mathematically it can be expressed in Cartesian reference frame as

$$x = \lambda^x x' \text{ and } y = \lambda^y y' \quad (48)$$

Examples include cauliflower, a cobweb, fern leaves, cantor set, and Koch curve. On the other hand, a self-affine fractal requires different scaling on either axis, to retain its geometry, in the sense that the variation in one axis scales differently

Signal Processing in Geosciences, Fig. 6 Figure showing (a) the structure of three-level decomposition of DWT, (b) original map of Kuwait City as test data, and (c) three-level wavelet decomposition of original image shown in (b)

from that on the other axis. Mathematically it can be expressed in Cartesian reference frame as

$$x = \lambda^\alpha x' \text{ and } y = \mu^\beta y' \quad (49)$$

where, λ , α , μ and β represent some non-zero constants. Examples include irregular curves and nonlinear timeseries of any dynamical system. The fractal dimension, D , for a self-similar set in $\mathbb{R}^n$ defines N nonoverlapping copies of itself

with each copy scaled down by a ratio $r < 1$ in all coordinates. Mathematically, it is expressed as

$$N = r^{-D} \Rightarrow D = \frac{\ln N}{\ln(1/r)} \quad (50)$$

Although a straight line, a square, and a cube satisfy the self-similar conditions described by Eq. (48), they are not fractals, since they have integer dimensions. Therefore, any

self-similar objects, which have noninteger dimensions only are said to be self-similar fractals. For more details on the estimation of fractal dimension for fractal structures, the reader is referred to Fernandez-Martinez et al. (2019). Fractal dimensions for self-affine irregular shapes and curves can be calculated using several techniques, some of which, we shall briefly discuss below.

It is important to note here that the concept of fractals is not limited to the study of geometrical shapes alone. It has rather wide applications in the study of different signals having a variation of some physical properties as a function of time. Since most geophysical timeseries represent the outcome of the behavior of any dynamical system, responsible for generating such nonstationary and nonlinear signals, they are expected to show self-affine behavior. In the case of timeseries analysis, different magnification factors are needed (along the vertical and horizontal axes), to compare the statistical properties of the rescaled and original timeseries, since these two axes represent different physical parameters: amplitude and time. Let us explain this further, as given below.

Consider a nonlinear data of length l_2 (Fig. 7a). A portion of the same data having length l_1 is expanded to a length, equal to l_2 (Fig. 7b). Now calculate the probability distribution of the data corresponding to window lengths l_1 and l_2 , and plot them as shown in Fig. 7c. s_1 and s_2 indicate the half-widths of the probability distribution curves corresponding to the data of lengths l_1 and l_2 , respectively. The relationship

between s_1, s_2 and l_1, l_2 is expressed by a parameter called, the *scaling exponent*, denoted by α , is given by

$$\frac{s_2}{s_1} = \left(\frac{l_2}{l_1}\right)^\alpha \quad (51)$$

The scaling exponent is estimated as shown in Fig. 7d. Likewise, α is calculated for different portions of the data with varying window lengths. If the α value is observed to be constant, indicating a steady increasing trend with the increasing window lengths, then that data is said to possess *monofractal* behavior. Alternatively, if the α values show different trends, with increasing window lengths, then that data is said to possess *multifractal* behavior.

Most observational data (generated by the dynamics of the unknown systems producing such nonlinear and nonstationary data) cannot be characterized by a single exponent throughout its length, and thus more than one scaling exponent are obtained for different segments within the same data based on the temporal variations in the statistical properties of the data. Such signals show multifractal behavior. Examples include seismological data, ionospheric data, geomagnetic data, and weather data, to name a few. While it is true that sometimes the nature of the data itself warrants its multifractal behavior, in most other cases, the effect of various types of noises that grossly vitiate the data, make it “behave” like a multifractal.

Signal Processing in

Geosciences, Fig. 7 Schematic representation of estimation of scaling exponent for a nonlinear data. (a) example nonlinear signal, (b) a portion of the signal expanded to be equal to the length of the original signal, (c) estimation of half-widths s_1 and s_2 of probability distribution function, $P(y)$ for the data corresponding to l_1 and l_2 windows, and (d) calculation of the scaling exponent, α

A few techniques to determine the scaling exponents for nonlinear and nonstationary data are (i) rescaled range (R/S) analysis, (ii) detrended fluctuation analysis (DFA) and (iii) multifractal DFA, and (iv) wavelet transform modulus maxima (WTMM) method. Let us briefly discuss each of them. For a full review of several other fractal and multifractal techniques, the reader is referred to Lopes and Betrouni (2009).

Rescaled Range (R/S) Analysis

This is also known as R/S technique, where R and S , respectively, denote the range and standard deviation of the integrated series generated from the given signal. This method basically relies on the fact that R and S bear a power-law relationship, defined as

$$\frac{R(k)}{S(k)} = k^H \quad (52)$$

where k designates the time length of the segment of the input signal, say $x(t)$. The integrated timeseries, y_k , of $x(t)$ is estimated as

$$y_k = \sum_{i=1}^k [x(i) - \bar{x}] \quad k = 1, 2, 3, \dots, N \quad (53)$$

The range, $R(k)$, defines the difference between the maximum and minimum of y_k , given by

$$R(k) = \max(y_0, y_1, y_2 \dots y_k) - \min(y_0, y_1, y_2 \dots y_k) \quad (54)$$

The standard deviation, $S(k)$, of the integrated series y_k , over the period k , is given by

$$S(k) = \frac{1}{k} \sqrt{\sum_{i=1}^k [y_i - \bar{y}]^2} \quad (55)$$

H in Eq. (52) is known as the *Hurst exponent*. The slope of the curve in the plot of the logarithm of the ratio of $R(k)$ to $S(k)$ Vs. the logarithm of k defines H . Figure 8a shows an example of interevent timeseries data generated from the earthquake magnitude (Mw) data (source: <http://www.isc.ac.uk/iscbulletin/search/catalogue/interactive/>) in the range, 4.0–4.9 of Japan region corresponding to a period between 1990 and 2016. Figure 8b shows the least-squares estimation of Hurst exponent value of 0.68, calculated using R/S analysis technique for the same data set, signifying the presence of persistent long-range correlations in the data. The Hurst exponent, H , is understood in the following way. (i) If $H > 0.5$, then the system behavior is called persistent. This suggests, an increasing (decreasing) trend in the past implies an increasing (decreasing) trend in the future. This is true for any natural phenomena, as in Fig. 8b. (ii) If $H < 0.5$, then the system behavior is called anti-persistent. This suggests, an increasing (decreasing) trend in the past implies a decreasing (increasing) trend in the future. Finally, (iii) if $H = 0.5$, then the correlation of the past and future increments vanishes at all times as required for an independent process, and thus the data represents the pure white noise series. More details about the Hurst exponent can be read from Bodruzzaman et al. (1991) and Gilmore et al. (2002).

Detrended Fluctuation Analysis (DFA) and Multifractal DFA (MFDFA)

DFA and MFDFA help to study the intrinsic self-similarities in nonstationary and nonlinear signals, by determining the scaling exponents in a modified least-square sense. In other words, they help to understand the order in the chaos. To estimate the scaling exponents through both these techniques, first the given signal is converted to a self-similar process by integration. This would help to bring out the power-law behavior in the signal, by making it unbounded, and detects the underlying self-similarities in the data over various

Signal Processing in Geosciences, Fig. 8 The test data (a) of interevent timeseries of earthquake magnitude (Mw) in the range, 4.0–4.9 of Japan region corresponding to a period between 1990 and 2016 and (b) Hurst exponent value calculated using R/S analysis technique

window lengths (Goldberger et al. 2000). Next, the integrated series is divided into short windows of equal length, and the local trend (a least-squares fit of chosen order) of the data corresponding to each window is calculated and removed from each data point of the respective window, and a fluctuation function corresponding to each window is calculated. This exercise is repeated for various chosen window lengths of the data. It is important to note here that after estimating the fluctuation functions with one window length, the successive window lengths are incremented by a factor of $\sqrt[3]{2}$, with the maximum window length not exceeding $N/4$, where N is the total number of data points in the signal under investigation (Peng et al. 1994). The fractal scaling exponent then signifies the slope of the linear least-squares regression between the logarithm of fluctuations and the logarithm of window lengths. In MFDFA, the above procedure is carried out repeatedly for different orders (also known as statistical moments) of fluctuation functions in a modified least-squares sense. The entire description of DFA and MFDFA techniques in simple mathematical steps is described below (see Kantelhardt 2002; Kantelhardt et al. 2002; Subhakar and Chandrasekhar 2016; Chandrasekhar et al. 2016):

1. First determine an integrated series $y(m)$ of N -point input data sequence, say $x(i)$, by

$$y(m) = \sum_{i=1}^m (x(i) - \bar{x}); m = 1, 2, 3, \dots, N \quad (56)$$

where, $\bar{x}$ denotes the mean of the N -point data sequence.

2. Divide the m -length integrated series into various m/k nonoverlapping windows of equal length, each consisting of k number of samples.

3. Calculate the least-squares fit of preferred order to the data points in each window. This represents the local trend, $y_k(m)$.
4. Detrend the integrated series, $y(m)$, by subtracting the local trend, $y_k(m)$, from each data point of the corresponding window.
5. For a window of length, k , the average fluctuation, $F(k, n)$, of the detrended series is calculated by

$$F(k, n) = \sqrt{\frac{1}{k} \sum_{i=s+1}^{nk} [y(i) - y_k(i)]^2} \quad (57)$$

where $s = (n - 1)k$; $N_k = \text{int}(m/k)$ and n denotes the window number.

6. Equation (57) is calculated for various window lengths, k . The power-law relation between $F(k, n)$ and k is given by $F(k, n) = k^\alpha$. The scaling exponent, α is estimated by

$$\alpha = \ln F(k, n) / \ln k \quad (58)$$

If α bears a linear relation between $\ln F(k, n)$ and $\ln k$, such that it steadily increases with increase in window length, for the entire data, then the data is said to possess *monofractal* behaviour. If α bears more than one linear relation between $\ln F(k, n)$ and $\ln k$, corresponding to a group of window lengths, as k increases, then the data is said to possess *multifractal* behavior. In other words, the data possessing multifractal behavior shows persistent short-range correlations up to a certain group of shorter window lengths and persistent long-range correlations for a group of larger window lengths. Fig. 9 depicts the examples of two different nonlinear mono and multifractal signals characterized by a single scaling exponent (Fig. 9a) and two scaling exponents (Fig. 9b), respectively.

Signal Processing in Geosciences, Fig. 9 Examples of two different nonlinear mono and multifractal signals characterized by (a) single scaling exponent and (b) two scaling exponents respectively (after Subhakar and Chandrasekhar 2015)

7. In MF DFA calculations, Eq. (57) is calculated by operating the windows in both forward and backward directions. For forward operations, n is considered as $n = 1, 2, 3, \dots, N_k$ and for backward operations, n is considered as, $n = N_k, N_k - 1, N_k - 2, \dots, 1$. Considering both forward and backward operations, the generalized form for overall average fluctuations is expressed as q^{th} order fluctuation function as (Kantelhardt et al. 2002).

$$F_q(k) = \left\{ \frac{1}{2N_k} \sum_{n=1}^{2N_k} [F^2(k, n)]^{\frac{q}{2}} \right\}^{\frac{1}{q}} \approx k^{h(q)} \quad (59)$$

Equation (59) is iteratively calculated for various k and q values to provide a power-law relation between $F_q(k)$ and $k^{h(q)}$. The Hurst exponent, $h(q)$, defined as

$$h(q) = \ln F_q(k) / \ln k \quad (60)$$

expresses the slope of the linear least-squares regression between the logarithm of the overall average fluctuations $F_q(k)$ and the logarithm of k , for corresponding q . q signifies the statistical moment, defined as mean ($q = 1$), variance ($q = 2$), skewness ($q = 3$), kurtosis ($q = 4$), etc. However, for better characterization of the signal, Eq. (60) is calculated for further upper and lower bounds of q , such that q can be negative also. Generally, q values considered in the range -8 to 8 are sufficient to meaningfully characterize any non-linear signal. In the range, $-q$ to $+q$, for the case of $q = 0$ (as the exponent becomes divergent at this value), Eq. (59) will be transformed to a logarithmic averaging procedure, given by (Kantelhardt et al. 2002).

$$F_0(k) = \exp \left[\frac{1}{4N_k} \sum_{n=1}^{2N_k} \ln \{F^2(k, n)\} \right] \approx k^{h(0)} \quad (61)$$

The behavior of multifractal Hurst exponent, $h(q)$, depends on the average fluctuations, $F_q(k)$. It bears a nonlinear relation with the order of the fluctuation function, q , such that the average fluctuations have high (low) $h(q)$ for negative (positive) q (Kantelhardt et al. 2002). If $h(q)$ varies (remains constant) for various q , then the signal is said to have multifractal (monofractal) behavior. This can be easily observed in Fig. 10, which depicts the q Vs $h(q)$ plot, obtained using synthetic data consisting of several periodicities (after Chandrasekhar et al. 2016). In Fig. 10, while the 1-day periodicity signal depicts monofractal behavior, the signals of all other periodicities exhibit multifractal behavior.

8. Finally, estimate the multifractal singularity spectrum, defining the relation between the singularity spectrum, $f(\alpha)$ and strength of the singularity, α , defined by

Signal Processing in Geosciences, Fig. 10 The q Vs $h(q)$ plot, obtained using synthetic data consisting of several periodicities, obtained using Eqs. 59, 60, and 61 (after Chandrasekhar et al. 2016)

Signal Processing in Geosciences, Fig. 11 A schematic representation of an example of multifractal (MF) singularity spectrum, depicting several parameters that aid in clear understanding of the spectrum. See the text for better understanding of the MF spectrum (after Chandrasekhar et al. 2016)

$$f(\alpha) = q[\alpha - h(q)] + 1 \text{ and } \alpha = h(q) + qh'(q) \quad (62)$$

α is also known as Hölder exponent. The reader is referred to Kantelhardt et al. (2002) for more details on α and $f(\alpha)$. Fig. 11 shows an example of $f(\alpha)$ versus α plot, known as multifractal singularity spectrum, depicting different parameters required to interpret the data. $\alpha_{\max} - \alpha_{\min}$ defines the width of the multifractal spectrum. The broader the width of the singularity spectrum, the stronger the multifractal behavior of the nonlinear data and vice versa (Kantelhardt et al. 2002). Also, in Fig. 11, the parameters **a** and **b** signify the distances of the extrema from the center of the spectrum. If **b** > **a**, then the spectrum is said to be right-skewed and if **a** > **b**, then the spectrum is said to be left-skewed. The right-skewed spectrum signifies the presence of finer structures in the data, and the left-skewed spectrum signifies the presence of coarser structures in the data. One easy way to understand this concept is as follows: If the multifractal singularity spectrum of the ECG signal of a heart patient is right-skewed, then the heart functioning is said to be good, indicating the

systematic heartbeat of the patient. However, if the spectrum is left-skewed, then the heart functioning is said to be not good, indicating the presence of large-scale and irregular fluctuations in the heartbeat, suggesting medical attention for that patient. This way, multifractal analysis helps to understand and interpret the factors contributing to the dynamics of the system, generating the nonlinear data.

Another important point to understand about the multifractal singularity spectrum is its positioning in the α Vs. $f(\alpha)$ plot. Calculating the multifractal spectra of a synthetic time series (the same synthetic data used for calculating $h(q)$ for Fig. 10), Chandrasekhar et al. (2016) have explained (see Fig. 12) that the positioning of multifractal singularity spectrum in the α Vs. $f(\alpha)$ plot corresponding to any periodicity in any given data is dictated by the number of cycles of that periodicity present in the data. If a fewer number of cycles of any periodicity are present in the data, then the multifractal spectrum corresponding to the data of that periodicity will be positioned at higher values of α and vice versa.

Applications The Hurst exponent, $h(q)$ (Eq. 60), plotted as a function of q , and the multifractal singularity spectra (Eq. 62), depicting the $f(\alpha)$ versus α plot, are the two important diagnostic information used in multifractal analysis to understand the fractal/multifractal behavior of the nonlinear and nonstationary data.

Telesca et al. (2004) applied the MFDFA algorithm on seismological data recorded for several years at three tectonically active zones in Italy. Multifractal studies helped them to easily demonstrate the differences in the subsurface dynamics in all the different zones. They also have compared their results with those of R/S analysis performed on the same data sets. Telesca et al. (2012) have also studied the environmental influences such as ocean effect and coast effect, on the magnetotelluric data recorded at different sites in Taiwan, using the MFDFA technique.

Signal Processing in Geosciences, Fig. 12 The α Vs $f(\alpha)$ plots, depicting the comparison of the position locations of the multifractal singularity spectra of different periodicities for the same synthetic data used in Fig. 10, obtained using Eq. (62) (after Chandrasekhar et al. 2016)

Subhakar and Chandrasekhar (2015, 2016) applied both DFA and MFDFA algorithms on geophysical well-log data of Bombay offshore basin (the same data used by Chandrasekhar and Rao (2012) for wavelet analysis) and identified the depths to the tops of formations and compared their results of DFA with those of wavelet analysis. Subhakar and Chandrasekhar (2016) also distinguished the oil and gas zones in the subsurface hydrocarbon reservoir zones, based on the multifractal behavior of well-log data. Further, they also explained whether the multifractal behavior in well-log signals is due to the presence of long-range correlations or the broad probability distribution in the data (Subhakar and Chandrasekhar 2015). Chandrasekhar et al. (2016) applied the MFDFA algorithm to ionospheric total electron content (TEC) data of a particular longitude zone covering both the hemispheres to understand the hemispherical differences in the spatiotemporal behavior of TEC and also the multifractal behavior of TEC recorded during the geomagnetically quiet and disturbed periods. Multifractal studies facilitated them to clearly demonstrate the semi-lunar tidal influences on TEC data as a function of latitude. Chandrasekhar et al. (2015) studied the multifractal behavior of geomagnetic field corresponding to geomagnetic quiet and disturbed days. They suggest that more geomagnetic data sets corresponding to different seasons would provide more comprehensive information on the multifractal behavior of the extraterrestrial source characteristics influencing the geomagnetic field variations during geomagnetic disturbed days. For other applications of multifractal analysis in the field of geomagnetism, the reader is referred to Hongre et al. (1999), Yu et al. (2009), and the references therein.

Wavelet-Based Multifractal Formalism: The Wavelet Transform Modulus Maxima (WTMM) Method

This method allows the determination of multifractal behavior of nonlinear dynamical systems using wavelets. This technique relies on the wavelet coefficients estimated from CWT. In this method, if the chosen mother wavelet has n vanishing moments, it will nullify all the polynomial trends of the order $n-1$ in the data (Daubechies 1992), leading to a natural detrending process (Vanishing moments of a wavelet signify the ability of the wavelet to suppress the polynomial trends in the given data. Higher vanishing moments imply the wavelet's ability to suppress the higher order trends in the data and vice versa.). This facilitates to accurately identify the singularities in the data. The “modulus” of the wavelet coefficients, obtained along the lines of maxima, can easily bring out the multifractal behavior of the data. (Lines of maxima are the curves formed by joining the points of local maxima at different scales in the wavelet scalogram (cf. Section “The Continuous Wavelet Transform (CWT)”). The convergence of lines of maxima at the lowest scale on the time axis

indicates the presence of singularities in the signal at those times). Mathematical details of the WTMM technique are as follows.

The multifractal behavior of a function, $f(t)$, around any point is characterized by the scaling properties of its local power law, given by

$$\langle |f(t+k) - f(t)| \rangle \approx k^{\alpha(t)} \quad (63)$$

The exponent $\alpha(t)$ describes the local degree of singularity or regularity around t . The collection of all the points that share the same singularity exponent is called the singularity manifold of exponent α and is a fractal set of fractal dimension $D(\alpha)$. The relation between $D(\alpha)$ and α signifies the multifractal singularity spectrum that fully describes the distribution of the singularities in $f(t)$.

The CWT of a function is defined by

$$Wf(u, s) = \langle f, \psi_{u,s} \rangle = \frac{1}{\sqrt{s}} \int_{-\infty}^{\infty} f(t) \cdot \psi^*\left(\frac{t-u}{s}\right) dt \quad (64)$$

The presence of the local singularity of $f(t)$ in a scalogram can be checked by the decay of $|Wf(u, s)|$ at t_0 on the time axis. The wavelet transform modulus maxima at a point (u_0, s_0) describes that $|Wf(u, s)|$ is locally maximum at $u = \pm u_0$, such that

$$\frac{\partial Wf(u_0, s_0)}{\partial u} = 0 \quad (65)$$

The modulus of the wavelet coefficients along the lines of maxima bears a power-law relationship with the scale corresponding to each identified singularity in the signal (Mallat 1999). Let (u_p, s) be the position of all local maxima of $|Wf(u, s)|$ at a fixed scale s . The global partition function, $Z(q, s)$, signifying the measure of the sum at a power q of all these wavelet modulus maxima is given by (Arneodo et al. 2008).

$$Z(q, s) = \sum_p |Wf(u_p, s)|^q \quad \text{where, } Z(q, s) \sim s^{\tau(q)} \quad (66)$$

q defines the statistical moment. The multifractal singularity spectrum from the wavelet transform local maxima can be obtained using $Z(q, s)$. The modulus of the wavelet transform and the set of maxima locations corresponding to scale s is given by (Mallat 1999)

$$|Wf(u, s)| \sim S^{(\alpha+1/2)} \text{ when } s \rightarrow 0^+ \quad (67)$$

From Eq. (66), the scaling exponent $\tau(q)$ can be obtained by

$$\log_2 Z(q, s) \sim \tau(q) \log_2 s \quad (68)$$

Finally, the multifractal singularity spectrum from the WTMM method is obtained by (Bacry et al. 1993).

$$D(\alpha) = \min_{q=R} [q(\alpha + 1/2) - \tau(q)] \quad (69)$$

For further illustration of the WTMM, the reader is referred to Arneodo et al. (2002, 2008) for numerous examples, Kantelhardt et al. (2002), Audit et al. (2002), and Salat et al. (2017) for comparison with the MDFA method. Using the cumulants of WTMM coefficients, Bhardwaj et al. (2020) studied the multifractal behavior of the ionospheric total electron content (TEC) data and established the consistent results obtained by Chandrasekhar et al. (2016) using MF DFA on the same data sets.

Empirical Mode Decomposition (EMD) Technique

Since most geophysical data are nonstationary and nonlinear in nature, the use of wavelet transformation, instead of the Fourier transform, has been proved to be one of the efficient techniques for characterizing the spatiotemporal nature of a variety of signals. However, the inherent problem with wavelet analysis lies with the identification of a suitable mother wavelet that best suits to analyze the signals. Besides wavelet analysis and the data-adaptive fractal and multifractal studies, another efficient and fully data-adaptive signal analysis technique, called the empirical mode decomposition (EMD) technique, can unravel the hidden information from the nonlinear signals. EMD technique, combined with Hilbert spectral analysis, is known as Hilbert-Huang transform (see Huang et al. 1998; Huang and Wu 2008). The EMD technique decomposes the data into oscillatory signals of different wavelengths, known as intrinsic mode functions (IMFs), just the similar way the discrete wavelet transform (DWT) decomposes the signal into detailed and approximate wavelet coefficients, representing the high- and low-frequency components of the signal respectively. However, the advantage of EMD technique over the DWT is that in the former, the decomposition of the signal into IMFs is easily done through some simple sifting operations, which are totally data-adaptive, unlike in the latter, where a similar operation necessitates an arduous task of choosing suitable wavelet and scaling functions. Although the EMD technique lacks a thorough mathematical framework, it is proved to be best suited to analyze nonlinear and nonstationary signals (Huang et al. 1998; Huang and Wu 2008; Gairola and Chandrasekhar 2017) and also acts as an efficient filter bank (Flandrin et al. 2004).

Methodology to Estimate the IMFs by EMD Technique

The end result of the fully data-adaptive EMD technique is the decomposition of different frequency components of the

signal (from highest to lowest) till the signal becomes monotonic, which is called the residue and represents the overall trend of the signal. The sequential steps to determine IMFs are as follows:

1. Identify the local maxima and minima of the given signal, $x(t)$, with a cubic-spline interpolation of them to form upper and lower envelopes, respectively, and calculate their mean, m_1 .
2. Calculate the first proto-mode, x_1 given by $x_1 = x(t) - m_1$.
3. If x_1 still contains maxima and minima, repeat steps 1 and 2 to get $x_{11} = x_1 - m_{11}$. Accordingly, after k iterations, we shall have, $x_{1k} = x_{1(k-1)} - m_{1k}$. According to Huang et al. (1998), the stopping criteria for this iterative process are (i) the number of extrema and number of zero crossings must be equal to or differ at most by 1. (ii) m_1 should be zero for the entire signal. Condition (i) ensures that the signal under investigation should not contain any local fluctuations and condition (ii) ensures that the Hilbert transform estimates the correct instantaneous frequencies from the data.
4. Choose the stopping criterion as the normalized squared difference of the data after two successive sifting operations, given by

$$D_k = \frac{\sum_{i=1}^N (x_{k-1}(i) - x_k(i))^2}{\sum_{i=1}^N (x_{k-1}^2(i))}$$

where N denotes the total number of data samples. Generally, D_k should be as small as possible, say $D_k \leq 0.1$, for correct estimation of each IMF after k iterations. Once the stopping criterion is satisfied after the first set of k iterations, then the first IMF (IMF-1), signifying the highest frequency present in the data is determined. It is important to note here that the condition, $D_k \leq 0.1$, is rather arbitrary and largely depends on the data quality. Higher D_k limits can be set for poor quality data and vice versa (Gairola and Chandrasekhar 2017).

5. Calculate the residue, r_1 , by subtracting IMF-1 data from the original signal and repeat steps 1–4 above to determine IMF-2.
6. Repeat steps 1–5 to calculate the successive IMFs until the residue becomes monotonic, when no further IMFs could be extracted from the data. The original signal can be obtained by synthesizing all the IMFs and the residue, given by $x(t) = \sum_{i=1}^{n-1} \text{IMF}_i + r_n$, where n denotes the n^{th} number of iteration, at which r_n becomes monotonic.

Figure 13 depicts an example of a nonlinear test signal and the IMFs obtained by EMD technique. EMD technique has

found several applications in a variety of specializations in geophysics, such as magnetotellurics (Cai et al. 2009; Cai 2013; Neukirch and Garcia 2014), well-logging (Gairola and Chandrasekhar 2017, Gaci and Zaourar (2014), seismics (Battista et al. 2007; Xue et al. 2013; Jayaswal et al. 2021), fault detection in mechanical devices (Gao et al. 2008), atmospheric sciences (McDonald et al. 2007), and sequence stratigraphy (Zhao and Li 2015), to name a few. Dätig and Schlurmann (2004) discussed the limitations of HHT, while applying it to study irregular water waves. Gaci and Zaourar (2014) and Gairola and Chandrasekhar (2017) have also discussed the use of IMFs in quantifying the degree of subsurface heterogeneity from nonlinear signals.

The EMD technique suffers with the problem of spilling over of frequencies from one IMF into other IMFs, called *mode mixing*. Mode mixing mainly arises due to overshoot and undershoot in cubic spline interpolation of upper and lower envelopes, while estimating the IMFs. To address this problem, a minor variant of the EMD technique, called the ensemble EMD (EEMD), technique has been developed (Wu and Huang 2009; Torres et al. 2011; Gaci 2016). Basically, in EEMD, different white noise series are added into the signal at several sifting operations. Since the noise added at each operation is different, the resulting IMFs do not display any correlation with their adjacent ones, and thus spilling of frequencies from one IMF to another one can be arrested. However, the principle of all these techniques remains the same as that of EMD technique described above. Also, the applications of EEMD technique in geosciences have been very limited as of now.

Application of IMFs in Characterizing the Degree of Sub-surface Heterogeneity If two nonlinear signals are generated from two different heterogeneous systems, then generally it is natural to believe that the signal producing more number of IMFs must have been generated from a system having a higher degree of heterogeneity than the other, thereby qualitatively understanding the heterogeneity of the two systems generating such signals. However, while this may be true, sometimes, it is not an easy task to assess the heterogeneity in different systems, when signals generated from two different dynamical systems produce equal number of IMFs. In such situations, it becomes difficult to establish, which system is more heterogeneous than the other. A better understanding of the dynamics of such systems, generating such nonlinear signals, can be best achieved by carrying out the heterogeneity analysis (see Gaci and Zaourar 2014).

Heterogeneity analysis of the IMFs of nonlinear signals provides a quantitative estimate of the degree of heterogeneity of the dynamics of the system producing such signals. We earlier have explained that the EMD technique acts as a filter bank (Flandrin et al. 2004), just the similar way the discrete wavelet transform does (Mallat 1999). Therefore, according

Signal Processing in

Geosciences, Fig. 13 Schematic representation of a nonlinear test signal and the IMFs generated from it. Note that the first IMF (IMF-1) designates the highest frequency and the last IMF (IMF-8) depicts the lowest frequency present in the signal. The bottom most curve depicts the residue, which is a monotonic function (see the text), which cannot be decomposed into any further IMFs (after Gairola and Chandrasekhar 2017)

to the filter bank theory, there must exist a nonlinear relationship between the IMF number (m) and the respective mean wavelength (I_m) of each IMF, given by $I_m = k\rho^m$, where ρ designates the heterogeneity index and k is the constant (Gaci and Zaourar 2014). As the above relation between I_m and m explains, the estimated ρ values bear an inverse relation with the heterogeneity of the subsurface. Accordingly, smaller (larger) ρ values designate higher (lesser) heterogeneity of the system. The two-step procedure to determine ρ is as follows:

1. For each IMF, calculate the mean wavelength (I_m) defined as the ratio of the total number of points to the total number of peaks.
2. Draw a plot between the IMF number, m , and the logarithm of I_m . The antilogarithm of the slope of this line defines the heterogeneity index, ρ .

Figure 14 depicts an example of heterogeneity indices determined from the geophysical well-log data of two different wells having an equal number of IMFs (see Gairola and Chandrasekhar 2017). Since the value of the heterogeneity index of the data of the first well (Fig. 14a) is greater than that

of Fig. 14b, the subsurface of the former well is less heterogeneous than the latter. This has also been confirmed with the results of multifractal analysis of the same data sets (see Subhakar and Chandrasekhar 2016).

Summary

Fundamentals of signal processing techniques and their applications in various problems of geoscience research have been discussed. Starting from the basics of integral transforms to advanced levels of nonlinear signal analysis techniques, their theory and applications have been discussed. Particularly, the application of linear integral transforms, namely, the Fourier transform, Z-transform, and the Hilbert transform in geophysics, and the applications of nonlinear signal analysis techniques, such as wavelet analysis (CWT and DWT), fractal and multifractal analysis, empirical mode decomposition technique, and all of their roles in diverse fields of geosciences, such as solid earth geophysics, ionospheric studies, and geomagnetism, has been discussed. Exhaustive literature on all of the above techniques has also been provided for the benefit of the reader.

Signal Processing in Geosciences, Fig. 14 Linear regression between the logarithm of mean wavelength of each IMF and the respective IMF number for geophysical well-log data of two different wells. Since the heterogeneity index of the well-log data corresponding to the

first well (a) is greater than that of the second well (b), the subsurface of the former well is less heterogeneous than the latter (after Gairola and Chandrasekhar 2017)

Simulated Annealing

Jaya Sreevalsan-Nair

Graphics-Visualization-Computing Lab, International Institute of Information Technology Bangalore, Electronic City, Bangalore, Karnataka, India

Definition

Physical annealing with solids is a thermodynamic process used in metallurgy, where heating and controlled cooling are used for modifying the physical properties of a material. The crystalline solid is first heated and then left to cool slowly until it reaches its most stable and regular crystal lattice configuration, i.e., with minimum lattice energy, and is free of crystal defects. Annealing gives superior structural integrity of solids if the cooling is done sufficiently slowly (Henderson et al. 2003). Thus, the physical state of a material, broadly represented as a physical system, is measured using its internal energy. The state of the material, i.e., the system, is stable when its internal energy is minimum. The state transition occurs during the cooling schedule in one of the two ways, namely, (i) when the material goes to a lower-energy configuration, by design, and (ii) when it goes to an upper-energy configuration under a specific condition. The condition for the latter is that the transition has an acceptance probability higher than a random number between 0 and 1.

Simulated annealing (SA) is akin to the annealing process where a computational system finds the global minimum as an optimum in the solution space through local searches. Thus, SA is defined as an optimization method that is a local search meta-heuristic (Henderson et al. 2003). Optimization methods are a class of computational methods that find a solution that either maximizes or minimizes an objective function, where the state of the system being optimized reaches the maximum or minimum value in its optimal state. Meta-heuristics are strategies of searching for a sufficiently good solution to an optimization problem. SA is also an iterative algorithm which uses local search strategy using hill-climbing method. Hill-climbing methods involve transitions of the states of the physical system that worsen the objective function. That said, SA is focused on finding an *approximate* globally optimal solution, as opposed to a *precise* locally optimal solution. Thus, the hill-climbing moves help in escaping the local extrema. In each iteration, the annealing process requires identifying two solutions in the solution space, where the probability of the system changing from one state to another is computed, and the solutions are compared to select the one that improves the value of the objective function is chosen, for the next iteration. Such transitions are referred to as *improving solutions*. In a few cases, a solution that

deteriorates the objective function value referred to as a *non-improving solution*, is chosen only to escape the local optima, in favor of the search for the global optima. This characteristic of SA has made it a popular optimization tool for both discrete optimization problems as well as continuous variable problems.

Overview

While SA has been found to be used prior to the formal usage of its current name, the documented introduction of the method, that also coined the term, was by Kirkpatrick et al. in 1983. This original method has since then been improved, and now, these resulting methods form a class of algorithms that mimics the physical annealing process (Kirkpatrick et al. 1983) and also includes the use of hill-climbing. The other class of approaches includes those that solve the Langevin equations, which are stochastic differential equations, and the global minimum is marked as the solution (Henderson et al. 2003). Langevin equation describes how a system goes through state transitions under the influence of deterministic but fluctuating random forces and is also used for describing *Brownian motion*.

Every instance of SA has the following elements (Bertsimas and Tsitsiklis 1993):

- A finite set S of states.
- A real valued objective/cost function J defined on S such that $S^* \subset S$, where the global minimum of J lie in S^* .
- A set of neighbors of i given as $\mathcal{N}(i)$ with symmetric neighborhood relationship, i.e., $j \in \mathcal{N}(i)$ implies that $i \in \mathcal{N}(j)$, where $j \in S - \{i\}$.
- The *cooling schedule*, which is a monotonously decreasing function $T : Z \rightarrow (0, \infty)$, where Z is a set of positive integers, i.e., $Z \subseteq \mathbb{Z}^+$, where $T(t)$ is the temperature at time t , and the initial temperature is $T(t_0) = T_0$, which is a positive value.
- An initial state $i_0 \in S$.

The iterative algorithm has a nested loop (Henderson et al. 2003) where the outer loop is governed by the temperature, and the inner loop is governed by the local neighborhood of a chosen state in a specific iteration. For every iteration of the outer loop, a specific number of iterations of the inner loop is implemented, and a decrement of temperature occurs. The outer loop is terminated when the stopping criterion is met, e.g., a certain temperature is reached. There is a “current state” associated with each iteration of the outer loop, whose neighborhood is searched for better solutions within the inner loop. The “current state” in the first iteration of the outer loop is i_0 . In the inner iteration, the neighbors of the chosen iteration are considered for a transition, if it is an improving solution except in specific cases of avoiding the local

minimum. The transitions lead to the change of the “current state” of the outer loop. The transitions are selected using hill-climbing, in practice. SA has been used for several applications, including traditional optimization problems, e.g., graph partitioning, graph coloring, and the traveling salesman problem (TSP) (Bertsimas and Tsitsiklis 1993), and industrial engineering/operations research problems, e.g., flow shop and job shop scheduling and lot sizing (Henderson et al. 2003).

The standard SA has a few disadvantages, including (a) the computationally intensive and inefficient approach in finding the optimal solution and (b) its inflexibility in certain problems (Ingber 1993). Thus, throughout the evolution of the SA, several directions have been pursued to improve the algorithm and its usability. These include generalizability of hill-climbing algorithm, convergence, efficient implementation, its extensions, etc. (Henderson et al. 2003). Genetic algorithms have been used in speeding up SA (Ingber 1993). One such method is simulated quenching, where the cooling schedule is a logarithmic function to allow faster cooling (Ingber 1993). The computational efficiency can be improved using parallel implementation using multiple processing units, such as CPU and GPU. Specific strategies are required to run an inherently sequential algorithm, such as SA, using parallel methods. One such implementation uses speculative computing to impose multi-point statistics for generating stochastic models subject to constraints (Peredo and Ortiz 2011).

A variant of SA is the adaptive simulated annealing (ASA), which relies on importance sampling of the parameter space, as opposed to deterministic methods. There are several strategies to implement ASA, of which one is about deriving parameters for current iteration from previous iterations.

SA can also be extended to multidimensional case where the objective function is defined on a subset of a k -dimensional Euclidean space (Fabian 1997). This implies the neighborhood search has to be extended to k -dimensional space, where both deterministic and random search strategies can be used.

Applications

SA has been applied for several applications in geoscience and related domains since its inception. One such application is to being a feasible alternative for multi-objective land allocation (MOLA) (Santé-Riveira et al. 2008). Rural land-use allocation is a complex problem given the multi-functionality of land units and noncontiguous fragmentation owing to urbanization. Thus, the conflicting multiple objectives for land-use allocation includes evaluating land units for both its utility type (e.g., crop type being cultivated), the contiguity of the units, and the compactness of resultant single-use landmasses. Additionally, SA is compared against

other similar optimization methods, such as integer programming, with respect to its run-time efficiency for large-scale problems, which is the case for regions with 2000–3000 land units. The SA has been found to be superior to alternative methods such as hierarchical optimization, ideal point analysis, and MOLA. The efficiency of SA has been found to be improved when provided with good a priori land use areas.

Optimization of reconfigurable satellite constellations (ReCon) taking into consideration the satellite design and orbits is a multidisciplinary problem (Paek et al. 2019). A ReCon is significant in agile earth observation, where it is used for both regular Earth observation as well as disaster monitoring. It is a constrained optimization problem which included four constraints, namely, (i) global observation mode (GOM) coverage, (ii) regional observation mode (ROM) revisit time, (iii) constellation mass, and (iv) reconfiguration time. The threefold objective in optimizing a ReCon include (i) minimization of revisit access time and maximization of area coverage, (ii) minimization of initial launch mass of ReCon, and (iii) minimization of reconfiguration time. The variables corresponding to the constraints are known to demonstrate nonlinear behavior, owing to which closed-form models are not available. Among the different SA methods used for this optimization problem, the point-based method has been found to outperform the gradient-based one. Given the nonlinearity behavior of the variables, genetic algorithms perform slightly better than SA in giving more optimal solutions, for this application.

SA can be used in conjunction with other data analytic methods. For an application of flash-flood hazard mapping, SA is used for eliminating redundant variables from the classifier models, which include boosted generalized linear model (GLMBoost), random forest classifier (RFC), and Bayes generalized linear model (BayesGLM) used in an ensemble (Hosseini et al. 2020). The classification done in this application is based on the severity of the flash flood and is used for forecasting. SA has been used in a novel and effective way for feature selection here.

Future Scope

In a similar way of integrating SA in a data analytic process, there is increased interest in the use of SA in deep learning, of late (Rere et al. 2015). While deep learning has been effective in classification and feature learning, it has its limitations in the ease of training models. SA can be used in improving the performance of convolutional neural networks (CNNs), in lieu of using optimal deep learning using meta-heuristics. This work has shown improvement in the performance of the CNNs with SA, specifically in the reduction of classification error, albeit at the cost of higher computation time.

Overall, it can be concluded that simulated annealing continues to be used as a powerful optimization tool in

applications in geosciences and related domains. It has the potential to combine with newer data analysis methods to give improved results.

Definition

Simulation refers to the construction of computer-based models that represent natural phenomena. These models can

be stochastic in nature, where an underlying probabilistic framework defines the possible outcomes of the model, or they can refer to complex numerical modeling based on processes or physics principles. In this article, we refer to stochastic models built for geoscientific applications in a spatial context, where geostatistical methods are used to create multiple possible outcomes of the spatial distribution of different attributes. These outcomes are called realizations and are based on a random function model that is reproduced by a geostatistical method, or are defined algorithmically. In all cases, the goal is to properly characterize the spatial variability of one or more variables that represent the phenomenon.

Introduction

The application of geostatistical simulation has been significantly developed in geosciences to quantify and assess the variability at a local scale using conditional realizations, and model the uncertainty at unsampled locations (Journel 1974; Deutsch and Journel 1998; Chilès and Delfiner 2012; Mariethoz and Caers 2014; Sadeghi 2020) – see the ► “Uncertainty Quantification” chapter.

Geostatistical simulation methods can be used to characterize categorical and continuous variables. In the case of categorical variables, each location can take one and only one of K categories. For continuous variables, the variable can take a value in a continuous range, which depends on its statistical distribution. In both cases, the spatial continuity of the variable is characterized by variograms (see the ► “Variogram” chapter) or multiple-point statistics (see the ► “Multiple Point Statistics” chapter). Unlike interpolation methods where a single prediction is obtained at every location, and the predicted values do not reproduce the spatial variability of the phenomenon, geostatistical simulations honor the data at sample locations, reproduce the statistical distribution of the variable over the simulated domain, and impose the spatial continuity of the model over each realization, which allows the characterization of uncertainty over any transfer function that involves multiple locations in the domain simultaneously.

Methods

The simplest frameworks to create these stochastic models include the indicators approach, which can be used to characterize categorical and continuous variables, and the multi-Gaussian approach, which is the basis of several simulation methods for continuous variables, but can also be used for methods based on truncation rules to represent categorical variables. Algorithmically driven methods are based on

optimization (e.g., simulated annealing) and on reproduction of multiple-point statistics.

Indicator Approach

The indicator approach is based on coding the random variable as an indicator. This indicator variable can then be characterized by its indicator variogram or transition probabilities, and estimated with indicator kriging. The indicator kriging estimates the probability of prevalence of a given class in the case of categorical variables, or the probability of not exceeding a threshold, in continuous variables. These probabilities can be used to build the conditional distribution and draw simulated values in a sequential fashion (Alabert 1987; Journel 1989).

For a categorical variable S , where $S(u)$ can take one of K values $\{s_1, \dots, s_K\}$, K indicator variables are defined as:

$$I(u; k) = \begin{cases} 1, & \text{if } S(u) = s_k \\ 0, & \text{otherwise} \end{cases} \quad k = 1, \dots, K$$

The categorical random function S can be characterized by its statistical distribution, in particular its probability mass function, and by the direct and cross-indicator variograms (or transition probabilities):

$$\gamma_I(h; k, k') = \frac{1}{2} E\{[I(u; k) - I(u+h; k)] \cdot [I(u; k') - I(u+h; k')]\} \quad k, k' = 1, \dots, K$$

The probability of prevalence of any of the K categories at a particular location can be inferred by applying kriging (or cokriging) to the indicator variable for that particular category. For instance, the simple indicator kriging estimate at location u_0 is:

$$I(u_0; k)_{SK}^* = \left(1 - \sum_{j=1}^n \lambda_j\right) \cdot P_k + \sum_{j=1}^n \lambda_j \cdot I(u_j; k)$$

where P_k is the probability mass of category s_k , and the weights λ_j are determined by solving the simple indicator kriging system of equations:

$$\sum_{j=1}^n C_I(u_i, u_j; k) \cdot \lambda_j = C_I(u_i, u_0; k) \quad i = 1, \dots, n$$

where the indicator covariances C_I are inferred from the variogram γ_I that characterizes the indicator variable. The predicted conditional distribution can be built by combining the K estimates $I(u; k)_{SK}^*, k = 1, \dots, K$. This conditional

distribution can be used in a sequential framework for conditional simulation, as described later.

In the case of a continuous variable Z , where $Z(u)$ is characterized by its statistical distribution F_Z , a set of K indicator variables is defined as:

$$I(u; k) = \begin{cases} 1, & \text{if } Z(u) \leq z_k \\ 0, & \text{otherwise} \end{cases} \quad k = 1, \dots, K$$

where the thresholds z_k , $k = 1, \dots, K$ discretize the global distribution F_Z . The random function $Z(u)$ is characterized by

its spatial continuity through direct and cross-indicator variograms, and the conditional distribution at a particular location u_0 can be inferred by kriging (or cokriging) the indicators. The conditional cumulative distribution function is approximated by:

$$F_{Z \leq z_k}(u_0)^* = I(u_0; k)^*$$

As with the case of categorical variables (Fig. 1), these conditional distributions can be used in sequential simulation to create random fields that reproduce the spatial continuity of the variable.

Simulation, Fig. 1 Sequential indicator simulation (SISIM) representative realizations (#20, 40, 60, and 80) of 100 conditional realizations for four mineralized zones in Daralu copper deposit (SE Iran). (From Sojodehee et al. 2015)

Multi-Gaussian Approach

The multi-Gaussian approach relies on a distributional assumption to infer the properties of the random function (Goovaerts 1997). This greatly simplifies the inference and calculations. In most cases, this requires an initial transformation of the variable into a (standard) normal distribution that is assumed to behave as a multi-Gaussian variable:

$$Z = \varphi(Y), \text{ with } Y \sim N(0, 1)$$

The multi-Gaussian assumption for Y means that the joint

distribution of $Y(u), Y(u + h_1), \dots, Y(u + h_n)$ is a $(n + 1)$ -variate multi-Gaussian distribution for any n , that is:

$$f_{Y(u)\dots Y(u+h_n)}(y_0, \dots, y_n) = \frac{\exp\left(-\frac{1}{2}(\mathbf{y} - \boldsymbol{\mu})^T \boldsymbol{\Sigma}^{-1}(\mathbf{y} - \boldsymbol{\mu})\right)}{\sqrt{(2\pi)^{n+1} |\boldsymbol{\Sigma}|}}$$

where

$$\mathbf{y} = \begin{pmatrix} y_0 \\ y_1 \\ \vdots \\ y_n \end{pmatrix}, \quad \boldsymbol{\mu} = \begin{pmatrix} \mu_0 \\ \mu_1 \\ \vdots \\ \mu_n \end{pmatrix}, \quad \boldsymbol{\Sigma} = \begin{pmatrix} \sigma_{Y(u)}^2 & C_{Y(u)Y(u+h_1)} & \cdots & C_{Y(u)Y(u+h_n)} \\ C_{Y(u+h_1)Y(u)} & \sigma_{Y(u+h_1)}^2 & \cdots & C_{Y(u+h_1)Y(u+h_n)} \\ \vdots & \vdots & \ddots & \vdots \\ C_{Y(u+h_n)Y(u)} & C_{Y(u+h_n)Y(u+h_1)} & \cdots & \sigma_{Y(u+h_n)}^2 \end{pmatrix}$$

The vector $\boldsymbol{\mu}$ contains the means of the corresponding random variables, while $\boldsymbol{\Sigma}$ represents the covariances between pairs of random variables.

Under this assumption any conditional distribution is Gaussian in shape and its conditional mean and conditional variance can be inferred by simple kriging of the conditioning variables:

$$Y_{SK}^*(u) = \sum_{j=1}^n \lambda_j \cdot Y(u + h_j)$$

$$\sigma_{Y,SK}^2(u) = 1 - \sum_{j=1}^n \lambda_j \cdot C_{Y(u)Y(u+h_j)}.$$

As in the indicator framework, these conditional distributions can be used in sequential simulation to create random fields that reproduce the spatial continuity of the variable Y . These values can be back-transformed to the original units to create a random field of the original variable Z .

Sequential Simulation

The indicator or multi-Gaussian approaches facilitate the inference of the local distribution at a given location u , conditioned by a set of known values at locations $u + h_1, \dots, u + h_n$. A random field can be simulated by the recursive application of Bayes' law. Every newly simulated value

becomes a new conditioning point, leading to a set of spatially correlated points drawn from the joint multivariate (multi-point) distribution (Journel 1994).

Simulation Methods

Although the sequential simulation framework provides a general method to simulate categorical or continuous variables, there exist other methods to achieve similar results.

Categorical variables can be simulated with sequential indicator simulation, or by truncation of one or more multi-Gaussian fields, as in truncated Gaussian simulation (Matheron et al. 1987), and pluri-Gaussian simulation (Armstrong et al. 2003). The key in the last two methods is to determine the spatial continuity of the multi-Gaussian fields in order to obtain the continuity of the indicator variables, once the truncation rule is applied.

Continuous variables can be simulated with sequential Gaussian simulation (SGSIM- Fig. 2) (Sadeghi 2020), but many other methods exist to create multi-Gaussian random fields, such as turning bands (TBSIM- Fig. 3), matrix decomposition (LU simulation), and FFT moving average.

Additionally, multiple-point simulation methods (Mariethoz and Caers 2014), some of which also rely on the sequential framework, can also be used to impose more complex relationships that are not properly reproduced with the sole use of variograms, both in the case of categorical and continuous variables.

Simulation, Fig. 2 Several representative realizations obtained by SGSIM, along with their Etype (mean at every location over the realizations), and conditional variance (variance at every location over the realizations)

Furthermore, most methods can be extended to the multi-variate case, where more than one attribute can be simulated simultaneously, preserving the direct and cross-spatial correlation, by generalizing the inference of the conditional distribution with simple cokriging.

In practice, there are many implementation details associated to the simulation of variables in real applications. Dealing with trends and nonstationary features and modeling multivariate relationships that depart from the multi-Gaussian assumption are the most relevant problems.

Use of Simulated Realizations

The different realizations generated by any of the above methods should:

1. Reproduce the conditioning sample data at their locations
2. Reproduce the global histogram (or proportions) of the variable in a stationary domain
3. Reproduce the spatial continuity of the variable (variogram or multiple-point statistics)

These realizations are not locally accurate, but aim at reproducing the in situ variability of the attribute in space. Therefore, these realizations can be used to characterize the uncertainty around the expected value at every location. This requires processing an ensemble (or a set) of realizations, in order to assess the expected variability in any response. This means that every realization is passed through a transfer function to generate a unique response. The set of responses obtained from processing an ensemble of realizations reflects the uncertainty about that response.

The ensemble of realizations can thus be interrogated to answer many different questions, such as the probability of one location to exceed a threshold z_C , or the probability of a volume (i.e., a collection of point locations) to exceed that same threshold z_C . More complex transfer functions are used in practical applications in environmental sciences, geological engineering, mining, petroleum, and other disciplines. The transfer function may be a complicated function of multiple locations, as in the case of the flow of petroleum in an oil reservoir, or be linked to a nonlinear function of the attribute, such as when calculating the metal recovery in a mine. It can

Simulation, Fig. 3 TBSIM several representative realizations (#100, #500 and #900)

also depend on the production sequence and time frame if a net present value is computed.

The variability captured by the simulations translates in uncertainty in prediction and design, which can be accounted for to obtain a robust and resilient design of the extractive approach in a mine or a petroleum reservoir.

Summary or Conclusions

Geostatistical simulation provides tools to characterize the variability of attributes at unsampled locations, and a quantification of the uncertainty related to any transfer function over the attributes. Simulation works by adding the lost variability that estimation methods smooth out, thus trading the local accuracy by the reproduction of the spatial variability. There are many different simulation methods to characterize categorical and continuous variables, which can also be extended to the simulation of multiple variables. The resulting realizations honor the data at sample locations, reproduce the global histogram, and reproduce the spatial continuity. These realizations must be treated as an ensemble to assess any response variable. There is no single best realization. All of the valid realizations must be processed through the transfer function to obtain multiple responses. The collection of responses characterizes the uncertainty after the transfer function. This is the

case in geosciences, environmental, mining, and petroleum applications, where the response may depend on multiple locations simultaneously and even change with time, as in the case of the net present value. Geostatistical simulation is a powerful tool to address the uncertainty in geoscience projects and obtain robust optima in decision-making that account for such uncertainty.

Definition

Singular spectrum analysis (SSA) is a family of methods for time series analysis and forecasting, which seeks to decompose the original series into a sum of a small number of interpretable components such as trend, oscillatory components, and noise.

Introduction

Singular spectrum analysis (SSA) aims at decomposing the observed time series into the sum of a small number of independent and interpretable components such as a slowly varying trend, oscillatory components, and noise (Elsner and Tsonis 1996; Golyandina et al. 2001). SSA can be used, for example, for finding trends and seasonal components (both short and large period cycles) in time series, smoothing, and forecasting. When SSA is used as an exploratory tool, one does not need to know the underlying model of the time series.

The origins of SSA are usually associated with nonlinear dynamics studies (Broomhead and King 1986a,b), and over

time, the method has gained a lot of attention. As stated in (Golyandina et al. 2001), SSA has proven to be very successful in time series analysis and is now widely applied in the analysis of climatic, meteorological, and geophysical time series. Many variants of SSA exist. However, in the following, we focus on a specific SSA method, often referred to as *basic SSA*.

Singular Spectrum Analysis

We define $\mathbf{x} = \{x_t; t = 1, \dots, N\}$ for an observable time series. The SSA algorithm consists of the following four steps (Golyandina et al. 2018).

1. **Embedding:** First, the so-called $l \times k$ -dimensional *trajectory matrix*

$$\mathbf{T}(\mathbf{x}) = \begin{pmatrix} x_1 & x_2 & x_3 & \cdots & x_k \\ x_2 & x_3 & x_4 & \cdots & x_{k+1} \\ x_3 & x_4 & x_5 & \cdots & x_{k+2} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ x_l & x_{l+1} & x_{l+1} & \cdots & x_N \end{pmatrix} \quad (1)$$

is constructed. Here N is the time series length, l is so-called *window length* and $k = N - l + 1$. The trajectory matrix $\mathbf{T}$ is a linear map mapping $\mathbf{x} \in \mathbb{R}^N$ into a $l \times k$ -dimensional Hankel matrix, i.e., to $l \times k$ -dimensional matrix $\mathbf{X} = \mathbf{T}(\mathbf{x})$ with equal elements on the off-diagonals. Columns $\mathbf{x}_i = (x_i, \dots, x_{i+l-1})'$, $i = 1, \dots, k$, of $\mathbf{X}$ are called as *lagged vectors* of dimension l . Golyandina et al. (2001) suggests that l should be smaller than $N/2$ but sufficiently large so that l -lagged vector $\mathbf{x}_i$, $i = 1, \dots, k$, incorporates the essential part of the behavior in the initial time series $\mathbf{x}$.

2. **Decomposition:** Once the time series $\mathbf{x}$ is embedded into a trajectory matrix $\mathbf{X}$, it is decomposed into a sum of rank-1 matrices. Denote now $\mathbf{S} = \mathbf{X}\mathbf{X}'$ and write $\mathbf{S} = \mathbf{U}\mathbf{A}\mathbf{U}'$ for an eigendecomposition of $\mathbf{S}$. Here $\mathbf{A}$ is a $l \times l$ diagonal matrix with nonnegative eigenvalues, $\lambda_1 \geq \dots \geq \lambda_l$, as diagonal values and $\mathbf{U} = (\mathbf{u}_1, \dots, \mathbf{u}_l)'$, $\mathbf{u}_i \in \mathbb{R}^l$, is an $l \times l$ orthogonal matrix that includes the corresponding eigenvectors as columns. If we further write $\mathbf{v}_i = \mathbf{X}'\mathbf{u}_i / \sqrt{\lambda_i}$, $i = 1, \dots, d$, where $d = \text{rank}(\mathbf{X})$, then $\mathbf{X}$ can be decomposed into a sum of rank-1 matrices as follows:

$$\mathbf{X} = \sum_{i=1}^d \mathbf{X}_i = \sum_{i=1}^d \sqrt{\lambda_i} \mathbf{u}_i \mathbf{v}_i'. \quad (2)$$

Notice that $\mathbf{u}_i \in \mathbb{R}^l$ and $\mathbf{v}_i \in \mathbb{R}^k$ are left and right singular vectors of $\mathbf{X}$, respectively, and $\sqrt{\lambda_i} > 0$ are the

corresponding singular values. In SSA literature these ordered singular values are often referred to as the *singular spectrum*, thus giving the name to the method (Elsner and Tsonis, 1996). It is important to mention that the above method, where X is being decomposed into rank-1 components using singular value decomposition, is called basic SSA. In practice, also other decompositions can be used. For more details, see Golyandina et al., (2001), for example.

3. Grouping: In this step, the rank-1 components in decomposition (2) are grouped into predefined groups, where the group membership is described by a set of indices $I = \{i_1, \dots, i_p\} \subset \{1, \dots, d\}$, $p \leq d$. Then, the matrix corresponding to the group I is defined as $X_I = X_{i_1} + \dots + X_{i_p}$. If the set of indices $\{1, \dots, d\}$ is partitioned into m disjoint subsets $I_1, \dots, I_m$, $m \leq d$, then one obtains so-called *grouped decomposition* of matrix X :

$$X = X_{I_1} + \dots + X_{I_m}. \quad (3)$$

Especially, if $I_k = k$, for $k = 1, \dots, d$, the grouping is called elementary and the corresponding components in (3) are called elementary matrices. Furthermore, if only one group $I \subset \{1, \dots, d\}$ is specified, one proceeds by assuming that the given partition is $\{I, I^c\}$, where $I^c = \{1, \dots, d\} \setminus I$. In that case, X_I usually corresponds to the pattern of interest, while $X_{I^c} = X - X_I$ is treated as the residual.

4. Reconstruction: As final step, matrices X_{I_j} , $j = 1, \dots, m$, from decomposition (3) are transformed into new time series of length N . Reconstructed $\tilde{x}_{I_k}$ are obtained by sequentially averaging the elements of matrix X_{I_k} , $k = 1, \dots, m$, that lay on the off-diagonals, i.e.,

$$[\tilde{x}_{I_k}]_t = \frac{1}{|S_t|} \sum_{i+j=t+1} [X_{I_k}]_{i,j}, \quad (4)$$

where $|S_t|$ denotes the cardinality of the finite set $S_t = \{(i, j): i + j = t + 1\}$. In the literature, this process is known as *diagonal averaging*. If one applies the given reconstruction to all components in group decomposition (3) and, for simplicity of the notation, denotes $\tilde{x}_k := \tilde{x}_{I_k}$, $k = 1, \dots, m$, the resulting decomposition of initial time series x is given by:

$$x = \tilde{x}_1 + \dots + \tilde{x}_m. \quad (5)$$

In the case of basic SSA for univariate time series, the tuning parameters one needs to specify a priori are window length l and the partition of the set of indices. In more general SSA, the trajectory matrix, as well as its rank-1 decomposition, can be chosen more freely.

Separability

A central concept in SSA is separability, which to some extent ensures the validity of the method. Assume that one can decompose the time series into two univariate series, that is, $x = x_1 + x_2$. This representation is usually associated with a *signal plus noise* model, *trend plus the remainder* model, and other structured models. (Approximate) separability of the components x_1 and x_2 implies that there exists a grouping (see Step 4) such that reconstructed $\tilde{x}_1$ and $\tilde{x}_2$ are (approximately) equal to x_1 and x_2 , respectively, i.e., $\tilde{x}_i \approx x_i$, $i = 1, 2$. In basic SSA, the (approximate) separability corresponds to (approximate) orthogonality of the trajectory matrices.

Consider as an example a time series of length N . If N is large enough, the trend, which is a slowly varying smooth component, and periodic components are (approximately) separable and both are (approximately) separable from the noise. For illustration see Fig. 1, where a trend and a periodic component are separated from a noise component. In Fig. 1 (a), the trend is extracted using the first three significant elementary components, with window length size $l = 100$. In Fig. 1 (b), the seasonal component is extracted using the first six significant elementary components, with window length size $l = 150$. The extracted components are approximately equal to the theoretical trend and seasonal component.

In order to check the separability of the reconstructed components $\tilde{x}_1$ and $\tilde{x}_2$, with corresponding trajectory matrices $\tilde{X}_1$ and $\tilde{X}_2$, respectively, the normalized orthogonality measure given in (Golyandina et al., 2018) is:

$$\rho(\tilde{X}_1, \tilde{X}_2) = \frac{\langle \tilde{X}_1, \tilde{X}_2 \rangle_F}{\|\tilde{X}_1\|_F \|\tilde{X}_2\|_F},$$

where $\langle \cdot \rangle_F$ and $\|\cdot\|_F$ are Frobenius matrix inner product and norm, respectively. This orthogonality measure further induces dependence measure between two time series called *w-correlation* (Golyandina and Korobeynikov 2014). A large value of *w-correlation* between a pair of elementary components suggests that, in the grouping step, these should perhaps be in the same group. Furthermore, additive sub-series can be identified using the principle that the form of an eigenvector resembles the form of the sub-series produced by the eigenvector. For example, the eigenvectors produced by a slowly-varying component (trend) are slowly varying, and the eigenvectors produced by a sine wave (periodic component) are again sine waves with the same period (Golyandina and Korobeynikov 2014). Therefore, plots of eigenvectors are often used in the process of identification. For more details, see Golyandina and Korobeynikov (2014); Golyandina et al. (2018), for example.

Singular Spectrum Analysis, Fig. 1 Left: extraction of the polynomial trend in time series $x_t = (0.05(t-1)-5)^2 + y_t$, $t = 1, \dots, 200$, where y_t is $MA(0.9)$ process. Right: extraction of the oscillatory component in

time series $x_t = a_t y_t$, where $a_t = 1$, for $t = 1, \dots, 100$, $a_t = 0.9$ for $t = 101, \dots, 200$ and $a_t = 0.9^2$ for $t = 201, \dots, 300$. $y_t = (0.1(t-1)-5)^2 + z_t$, where z_t is $MA(0.9)$ process.

Prediction Using SSA

A class of time series especially suited for SSA are so-called *finite-rank* time series, where we say that the time series $\mathbf{x}$ is of finite-rank if its trajectory matrix is of rank $d < \min(k, l)$ and does not depend on window length l , for l large enough. In that case, under mild conditions, there exists one-to-one correspondence between the trajectory matrix of the time series $\mathbf{x}$ and a linear recurrent relation (LRR):

$$x_{t+d} = \sum_{i=1}^{d-1} a_i x_{t+i}, t = 1, \dots, N-d, \quad (6)$$

that governs the time series $\mathbf{x}$. Furthermore, the solution to LRR (6) can then be expressed as sums and products of polynomial, exponential, and sinusoidal components, whose identification leads to the reconstruction of trend and various periodic components, among others. If one applies obtained LRR (6) to the last terms of the initial time series $\mathbf{x}$, one obtains the continuation of $\mathbf{x}$ which serves as a prediction of the future.

The real-data time series are not in general finite-rank time series. However, if time series $\mathbf{x}$ is a sum of a finite-rank signal $\mathbf{x}_1$ and additive noise, then SSA may approximately separate the signal component, and one can further use the methods designed for analysis and forecasting of the finite-rank series, thus obtaining the continuation (forecast) of a signal component $\mathbf{x}_1$ of $\mathbf{x}$ Golyandina and Korobeynikov (2014); Golyandina et al. (2001). Such a problem is known as forecasting the signal (trend, seasonality...) in the presence of additive noise. The confidence intervals for the forecast can be obtained using bootstrap techniques. For more details, see Golyandina et al. (2001); Golyandina and Korobeynikov (2014).

Example

To illustrate the SSA method, we use the average monthly temperatures (in °C) measured at the Jyväskylä airport, in Finland, from 1960 to 2000. To perform basic SSA as described above, we use the R (R Core Team 2020) package *Rssa* (Golyandina et al. 2015). As suggested in Golyandina

et al. (2001), for extracting a periodic component in short time series, it is preferable to take the window length l proportional to the period. Thus, we take $l = 48$. After investigating the singular values and paired scatter plots of the left singular vectors, we identify the first component as depicting a slowly varying trend, and the grouped fifth and sixth components to depict the yearly seasonality of the average monthly temperature. The original time series is shown together with its decomposition into seasonal component, trend component,

and residuals in Fig. 2. As seen in Fig. 2, the seasonal component is clearly dominating. However, there exists also a trend that looks almost linear. Eliminating the noise and using only the reconstructed trend and yearly seasonality, we predict the average monthly temperature for years 2000 and 2001 based on the components shown in Fig. 2. The predictions together with the true observed values are shown in Fig. 3. Figure 3 shows that SSA can be used to predict the temperatures in Jyväskylä quite nicely. For more details and

Singular Spectrum Analysis, Fig. 2 Top to bottom: Average monthly temperature ($^{\circ}\text{C}$) at the Jyväskylä airport from 1960 to 2000, the reconstructed seasonal component with 12-month period, reconstructed trend component, and residuals.

Singular Spectrum Analysis,

guidelines for grouping and identification of trend and oscillatory components, we refer to Golyandina et al. (2001).

Extensions and Relations to Other Approaches

SSA has been extended to multivariate time series in which case it is known as multidimensional or multichannel SSA (M-SSA) and for the analysis of images where it is known as 2D singular spectrum analysis (2D-SSA).

While usually time series analysis is either performed in the time or the frequency domain, one can see SSA as a compromise, as a time-frequency method. For example, SSA can be seen as a method that chooses an adaptive basis generated by the time series itself while, for example, Fourier analysis uses a fixed basis of sine and cosine functions. For more detailed discussions and interpretations of SSA, we refer to Elsner and Tsonis (1996); Golyandina et al. (2001); Ghil et al. (2002).

Summary

Singular spectrum analysis (SSA) is a model-free family of methods for time series analysis, that can be used, for example, for eliminating noise in the data, identifying interpretable components such as trend and oscillatory components, forecasting, and imputing missing values. The method consists of the four main steps: embedding, decomposition, grouping, and reconstruction. The method is currently widely applied in the analysis of climatic, meteorological, and geophysical time series.

Definition

Singular physical processes include various types of mineralization, volcanoes, floods, rainfall, and landslides (Wang et al. 2012). The singularity method is a model to “characterise

anomalous behavior of such processes mostly resulting in anomalous amounts of energy release or material accumulation within a narrow spatial–temporal interval” (Cheng 2007).

Introduction

One of the main objectives in the analysis of data in geochemical exploration programs is the selection and application of suitable classification models to distinguish between signals related to the mineralization effects and other processes or sources, as well as controls on variation in background geochemical distributions (Carranza 2009; Najafi et al. 2014; Zuo and Wang 2016; Grunsky and de Caritat 2020; Sadeghi 2020; see the entry ► “Exploration Geochemistry”). In environmental or urban geochemistry, the objective is generally the separation of geochemical patterns related to anthropogenic contamination from those derived from natural or geogenic processes (Guillén et al. 2011; Demetriades et al. 2015; Zuluaga et al. 2017; Albanese et al. 2018; Thiombane et al. 2019). The data addressed in these cases is commonly presented in the form of geochemical maps at various scales, sampling densities, and sampling geometries (Darnley 1990; Sadeghi 2020).

Various mathematical and statistical models have been applied to regional geochemical data to reveal subtle geochemical patterns related to the effects of different styles of mineralization or variations in parent lithologies. Conventional statistical methods such as exploratory data analysis (Tukey 1977; Chiprés et al. 2009), weights of evidence (Bonham-Carter et al. 1988, 1989), and probability plots (Sinclair 1991) used for anomaly detection or the isolation of geochemical signals and patterns related to the effects of mineralization on regolith geochemistry have a number of limitations. This has encouraged investigation of less conventional alternatives to conventional parametric methods, including fractal modeling and geostatistical simulation to isolate such signals or patterns (Cheng et al. 1994; Gonçalves et al. 2001; Li et al. 2003; Lima et al. 2003; Carranza 2009; Zuo 2011; Sadeghi et al. 2012, 2015).

Geochemical distributions, including those derived from regional regolith geochemical mapping studies, have been shown to display fractal behavior at various spatial scales (Bölviken et al. 1992). Such geochemical patterns develop through a variety of processes over geological time. It is the superimposition of several element enrichment or depletion episodes that results in the final element concentration distributions displaying multifractal behavior, containing a hierarchy of geochemical dispersion patterns observed at local to continental scales within most sampling materials (Zuo and Wang 2016, 2019). Differences observed in the fractal characteristics of regolith geochemical patterns relate to a number of factors. Whereas the main factor is typically a variation in

parent lithology (Cheng 2014; Nazarpour et al. 2015; Cámara et al. 2016), variation may also relate to the effects of mineralization and the task of separating element concentrations and/or samples into the categories traditionally termed “anomalous” versus “background” (Cohen and Bowell 2014).

The concept of fractal geometry was introduced to explain self-similarity or self-affinity at various scales in natural systems with models based on power-law spatial distributions in data (Mandelbrot 1983). Fractal or multifractal models are derived from power-law relationships between variables, such as the observed relationship between element concentration and the number of samples exceeding a given concentration.

A fractal model can be represented in the general form:

$$N(r) = C r^{-D} : r > 0, D \in \mathbb{R} > 0$$

where r is a characteristic linear measure, $N(r)$ is the number of objects with characteristic linear measure $\geq r$ ($\equiv N(\geq r)$), C is a constant of proportionality (a prefactor parameter), and D is the generalized fractal dimension (Shen and Zhao 1998). Some parametric distributions in geochemical data are intrinsically fractal (Shen and Cohen 2005).

Fractal relationships manifest as linear segments on (log-log) plots of the chosen fractal characteristics, in similar fashion to the identification of populations displaying particular distribution types and determining their parameters via probability or Q - Q plots (Sinclair 1991). The fractal dimensions are represented by the slopes of straight lines fitted to corresponding plots (Spalla et al. 2010; Sadeghi et al. 2012; Khalajmasoumi et al. 2017). In geochemical data, the slope for a fractal dimension can be interpreted as a measure of the element enrichment intensity (Afzal et al. 2010; Bai et al. 2010; Sadeghi et al. 2012; Zuo and Wang 2016). A change in slope or line orientation results in a new representative population for the given variables. In regional regolith geochemical data, this may be associated with a change in processes (e.g., different parent lithologies) or the existence of atypical conditions (such as the influence of mineralization). The threshold values, classifying different populations, are the breakpoints of the straight lines on such log-log plots (Carranza 2009; Afzal et al. 2011), providing a relatively simple graphical means of splitting data into populations.

A growing range of spatial and parametric fractal methods has been applied to geochemical data, to associate univariate or multivariate fractal dimensions to specific geochemical processes or domains. Whereas statistically self-similar fractals are typically isotropic, some may be anisotropic and display patterns at various scales depending on spatial orientations (Turcotte 1997), if a spatial fabric exists within the data.

In general, geochemical landscapes (Fortescue 1992) contain multiple fractal dimensions in regional geochemical data and thresholds and may be considered as spatially intertwined sets of monofractals (Feder 1988; Stanley and Meakin 1988). This may also be applicable to patterns with continuous spatial variability (Agterberg 1994, 2001). The multifractal behavior of variables within geochemical landscapes can be associated with the distributions of the probability density and spatial distributions of geochemical data (Cheng and Agterberg 1996; Carranza 2009; Zuo et al. 2009; Zuo and Wang 2016). In large, regional geochemical datasets, geochemical populations associated with mineralization are typically small and distinct as mineralization is typically of limited areal extent and is generally geochemically very distinct from other “background” or non-mineralization-related populations.

In conventional parametric methods, outlying values are generally removed prior to development of models (such as regression analysis or factor analysis) as they may significantly bias models. This partly derives from many conventional methods assuming geochemical element distributions following a normal or “normalisable” distribution (Reimann and Filzmoser 1999; Limpert et al. 2001; Sadeghi et al. 2015). Geochemical concentrations in the majority of studies do not follow a normal distribution or are the summation of a large number of component populations that either appear *en mass* to exhibit normality or log-normality (Li et al. 2003; Bai et al. 2010; He et al. 2013; Luz et al. 2014; Afzal et al. 2010). *Q-Q* plots are also based on the normality of data distribution neglecting the shape and intensity of anomalous areas. Fractal modeling does not typically require or assume normality and is largely unaffected by the presence of even extreme outliers. Therefore, fractal methods are gaining preference over conventional parametric methods (Afzal et al. 2010). Depending on the method used, fractal modeling can simultaneously incorporate population as well as spatial distribution characteristics of geochemical data (He et al. 2013; Luz et al. 2014).

Some fractal models have been developed to distinguish between different populations in geochemical datasets. This is to characterize geochemical anomalous values that could be related to the effects of mineralization. Such fractal models are number-size (N-S) (Mandelbrot 1983) and its 3D equivalent (Sadeghi et al. 2012), concentration-area (C-A) and perimeter-area (P-A) (Cheng et al. 1994, 1996; see the entry ► “Concentration-Area Plot”), spectrum-area (S-A) based on the relation between power spectrum and the occupied area of geochemical data values (Cheng et al. 1999; see the entry ► “Spectrum-Area Method”), singularity (Cheng 1999; Daya Sagar et al. 2018) based on the singularity spectrum, concentration-volume (C-V) (Afzal et al. 2011), spectrum-volume (S-V) (Afzal et al. 2012), concentration-concentration (C-C) (Sadeghi 2021), concentration-distance from centroids (C-DC) (Sadeghi and Cohen 2021a), category-based

fractal modeling (Sadeghi and Cohen 2021b) simulated size-number (SS-N) (Sadeghi et al. 2015), and global simulated size-number (GSS-N) (Madani and Sadeghi 2019).

Most such models are based on the relation between element concentrations and geometrical properties such as area and perimeter. The S-A model is used to differentiate geochemical anomalies from background by spectral analysis in the frequency domain through Fourier series analysis (Cheng 1999). The singularity model is applied to characterize the uniqueness degree of geological and geochemical properties based on its ability to delineate target areas, which are smoothed by conventional contouring models (Cheng 2007, 2008, 2012; Cheng and Agterberg 2009; Zou et al. 2013; Zuo and Wang 2016).

In exploration geochemical data, changes in fractal dimensions, indicated by the fractal classification models and ensuing clustering of samples, are used to cluster or partition samples and areas in geochemical maps. In large-scale regional geochemical mapping, the different classes represent the effects of variation in parent lithology, regolith development, and some environmental factors. Populations that are influenced by the effects of mineralization or contamination are typically represented by small numbers of samples that have conventionally been referred to as “geochemical anomalies” and the remainder as representing local or general “background” populations.

Methodology: Singularity Model

Singularity modeling is a form of fractal/multifractal modeling, which has been proposed and developed by Cheng (1999) to use in remote sensing and satellite image processing, with further work by Cheng (2007) focusing on its application in the study of stream sediment geochemical data for prediction of undiscovered mineral deposits. Some other studies on geochemical anomaly recognition have been undertaken using this method; e.g., Cheng and Zhao (2011) proposed that geochemical anomalies could be recognized for mineral deposit prediction through singularity theory, which has been developed to characterize nonlinear mineralization processes; Cheng (2012) applied the singularity theory for mapping geochemical anomalies related to buried sources and for predicting undiscovered mineral deposits in concealed areas; Wang et al. (2012) proposed a tectonic-geochemical exploration model based on the application of singularity theory to fault data; Xiao et al. (2012) combined the singularity mapping technique and spatially weighted principal component analysis (PCA) to delineate geochemical anomalies; Arias et al. (2012) demonstrated the robustness of C-A multifractal model and singularity technique for enhancing weak geochemical anomalies, in comparison with TS methods; and Zuo et al. (2013) compared the robustness of

C-A and S-A fractal models to singularity analysis in order to delineate geochemical anomalies in covered areas. Moreover, Zuo and Wang (2016) published a review paper to discuss and compare the theories, benefits, limitations, applications, and relations of C-A, S-A, concentration-distance (C-D), and C-V multifractal models in addition to the singularity model, especially for use in the recognition of weak anomalies associated with buried sources.

In general, the singularity modeling has been developed based on local singularity exponent. Such exponents are calculated by creating a number of maps (e.g., geochemical maps) with different scales. Such calculations are applicable to quantify the element concentration/depletion scaling properties. Based on Cheng (2012), singularity model is highly applicable to define weak but complex anomalous areas associated with mineral deposits, especially in areas covered or concealed by deserts, regolith, or vegetation.

The singularity phenomenon can be described in both 2D and 3D spaces based on a power-law relation between area (A) or volume (V) occupied by the target mineralization and the target metal/element total amount in that area ($\mu(A)$) or volume ($\mu(V)$). Such relationships have been formulated as follows (Cheng 2007):

$$\text{For } 3D : \mu(V_i) \propto V_i^{\frac{2}{3}}$$

where α is the singularity index. The metal/element concentration in this equation can be defined as $C(V_i) = \mu(V_i)/V_i$, and consequently:

$$C(V_i) \propto V_i^{\frac{2}{3}-1}$$

The same process for 2D models would result in:

$$\mu(A_i) \propto A_i^{\frac{1}{2}}$$

Then,

$$C(A_i) \propto A_i^{\frac{1}{2}-1}$$

The singularity index can be calculated using the following equation (Liu et al. 2019):

$$X = c \cdot e^{\alpha-E}$$

where X depicts element concentrations, c represents a constant value, ε is the normalized distance measure, α is the singularity index, and E is the Euclidian dimension (usually 2 in geochemical anomaly mapping) (Agterberg 2012; Zuo et al. 2013). In order to estimate the singularity index, we can

Singularity Analysis, Fig. 1 Simplified geology of Cyprus showing the Troodos Ophiolite (TO) flanked by the younger Circum-Troodos Sedimentary Succession (CTSS) and coastal alluvium-colluvium deposits (Sadeghi 2020; after Cohen et al. 2011)

apply window-based methods. The process of estimating the singularity index has been discussed in detail in Cheng 2007, 2012 and Zuo et al. 2013.

The main point here that needs to be taken into account is that anomalous positive singularity index values (with $\alpha < 2$) and those with negative singularity index values (with $\alpha > 2$) are usually associated with enrichments and depletions of element concentrations, respectively. However, when $\alpha \approx 2$,

there is no positive or negative geochemical singularity (Xiao et al. 2012).

Case Study: Cyprus

Sadeghi (2020) applied the singularity model to the high-density soil geochemical atlas of Cyprus (GAC) with the

Singularity Analysis, Fig. 2 Location of Cyprus-style VMS Cu deposits and mines, the host basalt units and the 5,515 soil sampling locations (Sadeghi 2020)

Singularity Analysis, Fig. 3 Classified singularity model of the Cyprus-style VMS Cu mineralization in Cyprus (Sadeghi 2020, 2021)

objective to isolate patterns associated with the Cyprus-style Cu deposits (against a high but variable background Cu content in most of the lithologies hosting the mineral deposits) (Figs. 1 and 2).

Factor analysis was previously completed on the dataset by Cohen et al. (2011, 2012a,b). All significant factors are related to general lithologically controlled geochemical variations in the soil. At the scale of sampling undertaken, none of the factors could be related to either effects of mineralization or anthropogenic influences. So, the singularity model is applied to the third factor (Fig. 3). The model has strongly defined the highly anomalous areas including the relevant known mineral deposits and mines. Moreover, several other areas in eastern and SW Cyprus have been recognized that could be potential target areas for further exploration.

Summary and Conclusions

Singularity index, from a multifractal point of view, is applicable to quantify the amount of enrichment or depletion in mineralization. It is also applicable to generate characteristic maps of mineralization based on different classes from background to highly anomalous populations, especially in concealed, buried, and undiscovered areas. Phenomena such as mineralization have both spatial and temporal properties although, even in quite small areas or in short time, both properties can be defined by spatial and temporal singularity models.

Synonyms

Low-pass filter

Definition

Smoothing filters aim at improving the signal-to-noise ratio.

Consider real-valued images defined on a finite regular grid S of size $m \times n$. Denote this support $S = \{1, \dots, m\} \times \{1, \dots, n\} \subset \mathbb{N}^2$. Elements of S are denoted by $(i, j) \in S$, where $1 \leq i \leq m$ is the row, and $1 \leq j \leq n$ is the column, or by $s \in \{1, \dots, mn\}$. An image is then a function of the form $f: S \rightarrow \mathbb{R}$, i.e., $f \in S^{\mathbb{R}}$, and a *pixel* is a pair $(s, f(s))$.

A central notion in filters is that of a *neighborhood*. The neighborhood of any site $s \in S$ is any set of sites that does not include s , denoted $\partial_s \subset S \setminus \{s\}$, obeying the symmetry relationship $t \in \partial_s \Leftrightarrow s \in \partial_t$, where “ $\setminus$ ” denotes the difference between sets, i.e., $A \setminus B = A \cap B^c$, and B^c is the complement of the set B . Image filters on the data domain are typically defined with respect to a relatively small squared neighborhood of odd side ℓ of the form

$$\partial_{(i,j)} = \left(\left(\left[i - \frac{\ell-1}{2}, i + \frac{\ell-1}{2} \right] \times \left[j - \frac{\ell-1}{2}, j + \frac{\ell-1}{2} \right] \right) \right) \cap S \setminus (i,j). \quad (1)$$

“small” in the sense that $\ell \ll m$ and $\ell \ll n$. We define the mask on the support

$$M = \left[-\frac{\ell-1}{2}, \frac{\ell-1}{2} \right] \times \left[-\frac{\ell-1}{2}, \frac{\ell-1}{2} \right],$$

with (odd) side ℓ , and it is denoted h_M .

Figure 1a shows the image we will use to illustrate the effect of smoothing filters. The image has 235×235 pixels, and it shows the amplitude data of a polarimetric synthetic aperture radar, horizontal-vertical channel. The effect of speckle is evident, but it is possible to see linear features.

(a) Original image

(b) Middle horizontal transect

Smoothing Filter, Fig. 1 Original image and transect

The “perfect” filter would eliminate the speckle, while retaining the details. Figure 1b shows the values of pixels in line 128, i.e., the transect at the middle of the image. Although the image shows dark and bright regions in this transect, the individual observations hinder such information due to the presence of speckle.

Linear Filters

Consider $\Psi : S^{\mathbb{R}} \rightarrow S^{\mathbb{R}}$ an image transformation. It is said to be linear if for any pair of real numbers α, β and any pair of images $f_1, f_2 \in S^{\mathbb{R}}$, holds that $\Psi(\alpha f_1 + \beta f_2) = \alpha \Psi(f_1) + \beta \Psi(f_2)$. Linear filters belong to the class of linear transformations.

(a) Mean over 3×3

(b) Mean over 7×7

(c) Mean over 13×13

(d) Transects and zoom

Smoothing Filter, Fig. 2 Mean filtered images and transects: original data in lilac, 3×3 in teal, 7×7 in brown, and 13×13 in pink

They are defined by means of a mask, and they are also called *convolutional filters*.

The convolution of the image $f \in S^{\mathbb{R}}$ by the mask $h_M \in M^{\mathbb{R}}$ is a new image $g \in S^{\mathbb{R}}$ given by

$$g(i, j) = \sum_{-\frac{\ell-1}{2} \leq i', j' \leq \frac{\ell-1}{2}} f(i-i', j-j') h_M(i', j'), \quad (2)$$

in every $(i, j) \in S$, and it is denoted $g = f * h_M$.

(a) Median over 3×3 windows (b) Median over 7×7 windows (c) Median over 13×13 windows

(d) Transects and zoom

Smoothing Filter, Fig. 3 Median filtered images and transects: original data in lilac, 3×3 in teal, 5×5 in brown, and 7×7 in pink

If all the elements of the mask are nonnegative, then it is customary to say that the resulting filter is a “low pass filter.” This is related to the fact that, in the frequency domain representation, such filters tend to reduce the high-frequency content, which is mainly related to noise and to small details. In the following we will illustrate some of these filters, and their effect on the data presented in Fig. 1a.

The class of *mean filters* is defined by masks h_M where all or some values take the same (positive) value, being the rest zero. In order to preserve the mean value of the image f , the usual choice for this value is the reciprocal of the sum of entries of h_M , as presented in the following:

$$h_M^5 = \begin{pmatrix} 0 & 1/5 & 0 \\ 1/5 & 1/5 & 1/5 \\ 0 & 1/5 & 0 \end{pmatrix}, h_M^9 = \begin{pmatrix} 1/9 & 1/9 & 1/9 \\ 1/9 & 1/9 & 1/9 \\ 1/9 & 1/9 & 1/9 \end{pmatrix},$$

and $h_M^{169} = (h(i, j) = 1/169)$ in every $-6 \leq i, j \leq 6$.

Figure 2a, b, and c are the result of applying convolutions with masks h_M^9 , h_M^{49} , and h_M^{169} to the image shown in Fig. 1a. These filtered images show the typical effect of low-pass filters: The noise is reduced, but small details are also affected. The bigger the support of the mean filter is, the more intense both effects are.

The transect shown in Fig. 2d shows the effect of the mean filters. The detail presented in the inset plot illustrates how the noise reduction goes along with the blurring of sharp edges.

Statistical Filters

This kind of filters employs statistical ideas. Many of them also belong to the class of linear filters, but many others do not.

The median filter returns in each coordinate s the median value of the observations belonging to $\overline{\partial}_s$. Its effect is similar to that of the mean filter, but it tends to preserve better edges at the expense of not reducing the additive noise as effectively as the latter does. On the other hand, it is excellent for reducing impulsive noise. Figure 3a, b, and c show the effect of the median filter and how it varies according to the window size. Figure 3d shows the original and median-filtered values along the transect.

More Details

A more model-based approach can be found in the book by Velho et al. (2008). Other important references are the works by Barrett and Myers (2004), Jain (1989), Lim (1989), Gonzalez and Woods (1992), Myler and Weeks (1993), and Russ (1998), among many others. Frery and Perciano (2013) discuss these and other filters, and how to implement them, while Frery (2012) discusses their properties and applications to digital document processing.

Choosing or designing a smoothing filter requires a good knowledge of both the kind of data and noise, and of the desired effect.

Summary

Smoothing filters aim at reducing noise while improving the signal-to-noise ratio. They often achieve such a task at the expense of introducing blurring and loosing details.

Definition

Spatial analysis is a quantitative study of spatial phenomena in geography and even earth science. Its main ability is to

manipulate spatial data into different forms and extract and mine potential information and knowledge. Spatial analysis derives from geographic information science (GIScience) and has been expanded and applied to a wide range of fields, including geoscience, architecture, environmental science, etc. Spatial analysis has been a core of Geographic Information System (GIS). Spatial analysis capability, especially to the extraction and transmission of spatial hidden information, is the main sign of GISs that differ from other information systems.

Situation and Development of Spatial Analysis Technologies

Since the appearance of maps, people have consciously or unconsciously carried out various types of spatial analysis. For example, measuring the distance and area between geographic elements on the map, and using the map for tactical research and strategic decision-making. With the application of modern computer technology into cartography and geography, geographic information system (GIS) began to gestate and develop. Digital maps stored in the computer show a broader application field. Using computers to analyze maps, extract information, discover knowledge, and support spatial decision-making has become an important research content of GIS. “Spatial Analysis” has also become a specialized term in this field. Spatial analysis is the core and soul of GIS, and it is one of the main signs of GISs differing from other information systems (Cressie and Wike 2015). Spatial analysis, combined with the attribute information of spatial data, can provide powerful and abundant analysis and mining functions for spatial data. Therefore, the position of spatial analysis in GIS is self-evident. So far, GIS and spatial analysis technologies have been applied in a wide range of fields including earth science, architecture, environmental science, social science, etc. (Fotheringham and Rogerson 2013).

Spatial analysis aims to obtain derivative information and new knowledge from the relationship between spatial object. It is a complex process of extracting information from one or more spatial data sources (Burrough 2001). Spatial analysis uses geographic computing and spatial characterization to mine potential spatial patterns and knowledge. Its essence includes 1) detecting patterns in spatial data, 2) studying the relationship between multivariate data and establishing spatial data models, 3) making spatial data more intuitive to express its potential meaning, and 4) improving the prediction and control capabilities of geospatial events. Obviously, spatial analysis mainly uses the joint analysis of spatial data and spatial models to mine the potential information among spatial objects. The basic information of these spatial objects consists of their spatial location, distribution, form, distance,

orientation, topological relationship, etc. Among them, distance, orientation, and topological relationship constitute the spatial relationship of spatial objects. It is the spatial characteristics between geographic entities and can be used as the basis for data organization, query, analysis, and reasoning. Combining the spatial data and attribute data of the spatial objects can perform spatial calculation and analysis of many specialized tasks (De Smith et al. 2018). Many spatial analysis methods have been implemented in GIS software. For instance, a large number of spatial analysis tools have been integrated in ArcToolBox, such as spatial information classification, overlay, network analysis, neighborhood analysis, geostatistical analysis, etc. (Fischer and Getis 2009).

Research Objects

Spatial analysis is a general term for related methods of analyzing spatial data, and it is a sign of the advancement of GISs. Early GISs emphasized simple spatial query, and the analysis functions were really weak. With the development of GIS, users need more and more complex spatial analysis functions. These requirements promote the development of spatial analysis technology and also make a variety of spatial analysis functions. According to the different features of spatial data, it can be divided into: ① analysis operation based on spatial graphic data; ② data operation based on non-spatial attributes; ③ joint operation of spatial and non-spatial data. The basis of spatial analysis is geospatial data. Its main goal is to use a variety of geometric logic operations, mathematical statistical analysis, algebraic operations, and other mathematical methods to solve the actual problems of geographic space.

Main Contents

Spatial analysis involves a variety of contents, which can be summarized into the following types.

1. Spatial location: the location information of a spatial object is transferred by means of the spatial coordinate system. It is the foundation of spatial object characterization.
2. Spatial distribution: group positioning information of similar spatial objects, including distribution, trend, comparison, etc.
3. Spatial morphology: geometric form of spatial objects.
4. Spatial distance: the proximity of space objects.
5. Spatial relationship: related relationship of spatial objects, including topology, orientation, similarity, correlation, etc.

Basic Methods

Spatial Query and Measurement

Spatial query is to obtain the location and attribute information of the spatial objects according to certain conditions to form a new data set. Spatial query methods can be divided into the following types: a) Location query, b) Hierarchical query, c) Regional query, d) Conditional query, and e) Spatial relationship query. There are a variety of spatial relationships between spatial entities, including topological, sequence, distance, orientation, and so on. Querying and locating spatial entities through spatial relationships is one of the features of GISs that are different from other information systems. Generally, GIS software has the function of measuring points, lines, and areas. Spatial measurement has different meanings for different points, lines, and areas. a) Point features (0D): coordinates; b) Linear features (1D): length, direction, curvature; c) Area features (2D): area, perimeter, shape, etc.; d) Body features (3D): volume, surface area, etc.

Buffer Analysis

Buffer analysis is one of the spatial analysis tools to quantify the proximity problem of geospatial objects. It aims to automatically build a set of polygons around points, lines, areas, and other geographic entities. Proximity describes how close two geospatial objects are. In reality, buffer zones reflect a range of influence or service area of a geospatial object. According to the features of geospatial objects (point, line, area, and body), the corresponding buffer analysis methods have been developed.

Overlay Analysis

The overlay analysis of GIS is the operation of superimposing the data composed of related thematic layers to generate a new data layer. The result is a synthesis of the attributes of the original two or more layers. Overlay analysis includes not only the comparison of spatial relationships, but also the comparison of attribute relationships. Overlay analysis can be divided into the following categories: visual information overlay, points and polygons overlay, lines and polygons overlay, polygons overlay, and raster overlay. Logical operations are commonly used in overlay analysis, and logical expressions are used to analyze and process the logical relationships between geospatial objects from different layers.

Network Analysis

Network analysis is a basic model in operations. Its fundamental purpose is to study and plan how to arrange a network and make it run best (Okabe and Sugihara 2012). The analysis and modeling of geospatial networks (such as transportation

networks) and urban infrastructure networks (such as various network cables, power lines, telephone lines, water supply and drainage pipelines, etc.) are the main objects of GIS network analysis. The basic idea is that human activities always tend to choose the best spatial location according to a certain goal. Such problems are numerous in social and economic activities, so it is of great significance to study network problems in GIS. Network analysis includes: path analysis (seeking the best path), address matching (essentially a query of geospatial locations) and resource allocation.

Spatial Statistical Analysis

Due to the interaction between spatial phenomena in different directions and different distances, traditional mathematical statistics cannot well solve the problems of spatial sampling, spatial interpolation, and the relationship between two or more spatial datasets. Therefore, the methods of spatial statistical analysis emerged. In the 1960s, Matheron formed a new branch of statistics through a lot of theoretical research, namely, spatial statistics, also called geostatistics (Matheron 1963).

Spatial statistics is based on the theory of regionalized variables. It uses the variograms as the main tool to study the spatial interaction and change laws of geospatial objects or phenomena (Unwin 1996). The spatial statistical methods assume that all the values in the study area are non-independent and correlated with each other. In the context of space or time, it is called autocorrelation. By detecting whether the variation in a position depends on the variation of other positions in its neighborhood, it can be used to judge whether the variation bears spatial autocorrelation. The important task of spatial statistical analysis is to reveal the correlation rules of spatial data and use these rules to predict unknown points. Spatial statistics contains two significant tasks: 1) analyzing the variograms or covariograms of spatial variability and structures and 2) Kriging interpolation for spatial local estimation.

Spatial interpolation is to generate a continuous surface using samples collected at different locations. Kriging is the most common and widely used spatial interpolation method. Kriging and its variants are based on the theoretical analysis of variogram or covariogram. They are methods for unbiased and optimal estimation of regionalization variables in a limited area.

Conclusions and Outlook

Spatial analysis is a spatial data analysis technique based on the location and morphology of geospatial objects. Its

purpose is to discover, extract, mine, and transmit potential spatial information and knowledge. Spatial analysis technology has been applied in many fields including geography, geology, surveying and mapping, architecture, environmental science, and social science. Different application fields present different meanings to spatial analysis. Their emphasis is different, but they all explain the connotation of spatial analysis from different aspects: either focusing on geometric analysis, or focusing on geostatistics and modeling. In summary, GIS spatial analysis is a technology that uses geometric analysis, statistical analysis, mathematical modeling, geographic calculation, and other methods to describe, analyze, and model the spatial relationship of in geospatial entities, and further provide services for spatial decision.

Especially, spatial statistics or geostatistics has become the basis of quantitative research in geosciences. Geostatistics is widely used in the characterization of complex heterogeneous geological phenomena and structures, mapping the prospect of mineral resources, reserve calculation of mineral resources, reservoir prediction and simulation, etc. With the further development of artificial intelligence and big data technologies, using artificial neural networks, machine learning, and deep learning technologies to mine and analyze the deeper correlations and knowledge hidden behind the massive data has become the hotspots and key issues in the joint field of mathematical geoscience and GIS.

Spatial Autocorrelation

Donato Posa and Sandra De Iaco

Department of Economics, Section of Mathematics and Statistics, University of Salento, Lecce, Italy

Synonyms

Covariance function; Spatial correlation; Variogram

Definition

Spatial autocorrelation is an assessment of the correlation between two random variables which describe the same aspect of the phenomenon under study, referred to two locations of the domain. The suffix “auto” is justified since in some sense the spatial autocorrelation quantifies the correlation of a variable with itself over space. However, the expressions “spatial autocorrelation” and “spatial correlation” are used interchangeably in literature. Most of the theoretical results of classical statistics consider the observed values, as independent realizations of a random variable: this assumption makes the statistical theory much easier. Unfortunately, this last hypothesis cannot be valid if the observations are measured in space (or in time). Historically, the concept of spatial autocorrelation has naturally been considered an extension of temporal autocorrelation: however, time is one-dimensional, and only goes in one direction, ever forward, on the other hand, the physical space has (at least) two dimensions.

Any subject which regards data collected at spatial locations, such as soil science, ecology, atmospheric science, geology, image processing, epidemiology, forestry, astronomy, needs suitable tools able to analyze dependence between observations at different locations.

A Brief Overview

In the last years, spatial data analysis has developed peculiar methods to provide a quantitative description of several spatial variables in various fields of applications, from environmental science to mining engineering, from medicine to biology, from economics to finance and insurance.

The present contribution will be devoted to spatial autocorrelation for *geostatistical data*: indeed, besides *geostatistics*, distributions on *lattices* and *spatial point processes* are considered further branches of spatial statistics. In

particular, geostatistical data refer to observations related to an underlying spatially continuous phenomenon, i.e., to measurements which can be taken at any point of a given spatial domain and utilize the formalism of the random functions (RFs) (Christakos 2005; Journel and Huijbregts 1981; Matheron 1971). Most of the applications use the variogram or the covariance function to characterize spatial correlation. A further and more general development to geostatistical methods has been provided by the theory of the *intrinsic random functions of order k* (Matheron 1973) and by *multiple point geostatistics* (Krishnan and Journel 2003).

Although real-valued covariance functions have been mostly utilized in several applications, it should be properly underlined that a covariance, according to Bochner's theorem, is a complex valued function: this relevant aspect is often neglected. For this purpose, in recent years, a significant and more general contribution to the theory of spatial autocorrelation has been given thanks to the formalism of *complex RFs*, which generalize the theory of real RFs (Posa 2020); indeed, the theory of complex valued RFs provides an important contribution in the study of various phenomena in oceanography, signal analysis, meteorology, and geophysics. In particular, in the last part of this entry, it will be underlined which tools of spatial autocorrelation are more appropriate and suitable, according to the various and different case studies.

Real Valued Random Functions

Geostatistical techniques rely on the theory of RFs: in particular, in the whole first part of the entry the discussion will be devoted to real valued RFs, whereas in the last part of the entry, a brief outline on complex valued RFs will also be given.

Consider the value $z(\mathbf{s})$, $\mathbf{s} \in D$, of a spatial variable z (which belongs to the set of the real numbers), where $\mathbf{s}$ is the vector of the spatial location and D is the spatial domain. Any sampled measure $z(\mathbf{s})$ with $\mathbf{s} \in D$ is considered as a realization of the random variable $Z(\mathbf{s})$. The set of all random variables over the domain D is called RF. Hence, the sampled values of a spatial phenomenon can be interpreted as a finite realization of a spatial RF (SRF), i.e.,

$$\{Z(\mathbf{s}); \mathbf{s} \in D\}, D \subseteq \mathbb{R}^n, \quad n \in \mathbb{N}_+. \quad (1)$$

By assuming the existence of the first and second order moments for Z , the SRF can be decomposed as follows:

$$Z(\mathbf{s}) = \mu(\mathbf{s}) + Y(\mathbf{s}), \quad (2)$$

where $\mu(\mathbf{s}) = E[Z(\mathbf{s})]$ is the expected value of Z , usually called drift, and Y is a zero mean SRF, which describes the random

fluctuations (or the micro scale variability) of the phenomenon under study around the expected value.

In applied sciences usually the distribution function which characterizes the SRF is unknown and cannot be derived empirically due to the small number of realizations (in most cases only one sequence of measurements is available). Thus, the characterization of the SRF is limited to its statistical moments of order up to two. The part of the general theory that studies the properties of a SRF utilizing only the first and second order moments is called *correlation theory*. In particular, the expected value μ (moment of first order), the covariance C , and the semivariogram γ (moments of second order) of an SRF Z are defined, respectively, as follows:

$$\mu(\mathbf{s}) = E[Z(\mathbf{s})], \quad \mathbf{s} \in D, \quad (3)$$

$$C(\mathbf{s}_i, \mathbf{s}_j) = E[(Z(\mathbf{s}_i) - \mu(\mathbf{s}_i))(Z(\mathbf{s}_j) - \mu(\mathbf{s}_j))], \quad \mathbf{s}_i \in D, \quad \mathbf{s}_j \in D, \quad (4)$$

$$2\gamma(\mathbf{s}_i, \mathbf{s}_j) = \text{Var}[(Z(\mathbf{s}_i) - Z(\mathbf{s}_j))], \quad \mathbf{s}_i \in D, \quad \mathbf{s}_j \in D. \quad (5)$$

Note that 2γ is called *variogram* and differs from the semivariogram by the constant.

Stationarity

Stationarity is a prior decision which refers to the SRF, not to the sampled values; this hypothesis makes inference possible from the observed values over the spatial domain D . The SRF Z is said to be stationary of order two, if its expected value exists and is independent of the location, its covariance C exists and depends only on the separation vector $\mathbf{h}$ between two spatial locations, i.e.,

$$E[Z(\mathbf{s})] = \mu, \quad \mathbf{s} \in D, \quad (6)$$

$$C(\mathbf{h}) = E[(Z(\mathbf{s} + \mathbf{h}) - \mu)(Z(\mathbf{s}) - \mu)], \quad \mathbf{s} \in D, \mathbf{s} + \mathbf{h} \in D. \quad (7)$$

As a consequence, even the semivariogram γ exists and depends only on the separation vector $\mathbf{h}$ between two spatial locations, i.e.,

$$2\gamma(\mathbf{h}) = E[(Z(\mathbf{s} + \mathbf{h}) - Z(\mathbf{s}))^2], \quad \mathbf{s} \in D, \mathbf{s} + \mathbf{h} \in D. \quad (8)$$

In case of a stationary random field, the covariance function, which is represented by a one-parameter function, is called *covariogram*. The covariance function usually decreases when the distance between two spatial locations increases; on the other hand, the semivariogram, by definition, is a variance, hence it usually increases when the distance between two spatial locations increases. It is well known that the covariance C and the semivariogram γ are connected through the following relationship:

$$\gamma(\mathbf{h}) = C(\mathbf{0}) - C(\mathbf{h}). \quad (9)$$

A detailed and interesting overview and comprehensive discussion about stationarity is given in Myers (1989). Note also that the variogram and the covariance functions are the main tools utilized to describe the spatial dependence; moreover, the corresponding models are used to make predictions.

Intrinsic Hypotheses

A weaker stationarity hypothesis, often recalled in the literature, assumes that, for every vector $\mathbf{h}$, the increment $(Z(\mathbf{s} + \mathbf{h}) - Z(\mathbf{s}))$ is second order stationary: in this case, Z is called an intrinsic RF (IRF), i.e.,

$$E[(Z(\mathbf{s} + \mathbf{h}) - Z(\mathbf{s}))] = 0, \quad 2\gamma(\mathbf{h}) = E[(Z(\mathbf{s} + \mathbf{h}) - Z(\mathbf{s}))^2].$$

Hence, the processes that satisfy the hypotheses of second-order stationarity are a subset of the processes that satisfy the intrinsic hypotheses. This aspect justifies why the semivariogram function γ is more utilized than the covariance function in several applications.

Intrinsic Random Functions of Order k

In geostatistics, it is well known that if there is a trend in the data, then a bias affects the variogram of the residuals in universal kriging. Historically, this has been the starting point to construct models in a such a way to reach stationarity by considering increments of higher order than the ones defined through the intrinsic hypotheses: indeed, these last are defined as IRF of order zero. Through the IRF of order k (IRF k) theory (Matheron 1973) a wider class of covariance functions (the generalized covariance functions) has been obtained and applied in order to overcome the bias, above mentioned, and to reach stationarity through a suitable order of increments. The theory of IRF k generalizes the approach utilized in time series (ARIMA models): indeed, Z is an IRF k , with $k \in \mathbb{N}$, if:

$$W(\mathbf{s}) = \sum_{i=1}^m \lambda_i Z(\mathbf{s}_i + \mathbf{s}), \quad \mathbf{s} \in D,$$

is second order stationary, where $\mathbf{s}_i \in D$, $i = 1, \dots, m$, and $A = (\lambda_1, \dots, \lambda_m)^T$ is a vector of real numbers such that $(f_j(\mathbf{s}_1), \dots, f_j(\mathbf{s}_m))A = 0$, where f_j , $j = 1, \dots, k + 1$, are mixed monomials.

The generalized covariances, which characterize IRF k , are even functions and are unique up to an even polynomial of degree $2k$. In summary, the RFs which are second order stationary are a subset of the RFs which are intrinsically stationary, i.e., IRF of order 0 (IRF0), and these last are a subset of IRF1 and so forth. A detailed discussion on IRF k , on the properties and construction of generalized covariances

can be found in Chiles and Delfiner (1999), in Christakos (1984) and in Cressie (1993).

Properties of Covariance and Semivariogram Functions

The family of the real covariance functions satisfies the following properties:

$$|C(\mathbf{h})| \leq C(\mathbf{0}), \quad C(\mathbf{h}) = C(-\mathbf{h}), \quad (10)$$

and then $C(\mathbf{0}) \geq 0$.

If C_i , $i = 1, \dots, n$ are covariance functions defined in $\mathbb{R}^n$ and a_i , $i = 1, \dots, n$ are non-negative coefficients, then C_P and C_S , defined as follows:

$$C_P(\mathbf{h}) = \prod_{i=1}^n C_i(\mathbf{h}), \quad C_S(\mathbf{h}) = \sum_{i=1}^n a_i C_i(\mathbf{h})$$

are covariance functions.

If $C_n(\mathbf{h})$, $n \in \mathbb{N}$ are covariance functions in $\mathbb{R}^n$, then $C(\mathbf{h}) = \lim_{n \rightarrow \infty} C_n(\mathbf{h})$ is a covariance function, if the limit exists.

If $C(\mathbf{h}; a)$ is a covariance in $\mathbb{R}^n$ for all values of $a \in A \subseteq \mathbb{R}$ and if $\mu(da)$ is a positive measure on A , then $\int_A C(\mathbf{h}; a) \mu(da)$

is a covariance function, if the integral exists for all $\mathbf{h} \in D$.

Moreover, the condition for a function to be a covariance is that it be positive definite, namely:

$$\sum_{i=1}^n \sum_{j=1}^n a_i a_j C(\mathbf{s}_i - \mathbf{s}_j) \geq 0 \quad (11)$$

for any $\mathbf{s}_i \in D$, any $a_i \in \mathbb{R}$, $i = 1, \dots, n$, and any positive integer n . The function C is strictly positive definite if it excludes the chance that the quadratic form in (11) is equal to zero $\forall n \in \mathbb{N}_+$, any choice of distinct points $(\mathbf{s}_i)$, $\forall a_i \in \mathbb{R}$ (with at least one different from zero). Note that strict positive definiteness is desirable, since it ensures the invertibility of the kriging coefficient matrix; a thorough discussion on strict positive definiteness for covariance functions is given in De Iaco and Posa (2018). A semivariogram function satisfies the following properties:

$$\gamma(\mathbf{h}) = \gamma(-\mathbf{h}), \quad \gamma(\mathbf{0}) = 0, \quad \lim_{\|\mathbf{h}\| \rightarrow \infty} \frac{\gamma(\mathbf{h})}{\|\mathbf{h}\|^2} = 0;$$

if γ_i , $i = 1, \dots, n$ are semivariogram functions defined in $\mathbb{R}^n$ and a_i , $i = 1, \dots, n$ are non-negative coefficients, then $\gamma_S(\mathbf{h}) = \sum_{i=1}^n a_i \gamma_i(\mathbf{h})$ is a semivariogram function. Moreover, a semivariogram is a conditional negative definite function, namely,

$$\sum_{i=1}^n \sum_{j=1}^n a_i a_j \gamma(\mathbf{s}_i - \mathbf{s}_j) \leq 0, \quad \sum_{i=1}^n a_i = 0 \quad (12)$$

for any $\mathbf{s}_i \in D$, $a_i \in \mathbb{R}$, $i = 1, \dots, n$, and any positive integer n .

Although a number of studies provide theoretical results in terms of the covariance, the spatial correlation is usually analyzed through the variogram, which is preferred to the covariance for different reasons (Cressie 1993).

Peculiar Features of Spatial Autocorrelation

Some relevant peculiar characteristics, such as isotropy, separability, and symmetry, concerning spatial autocorrelation will be described hereafter and will be given in terms of the covariance function. Note that the definition of isotropy can also be given in terms of the variogram; however, the definition of separability can only be described in terms of the covariance function. These special features, which are described in detail in (De Iaco et al. 2019), play an important role for the choice of a suitable correlation model for the spatial variable.

Isotropy/Anisotropies

Geostatistical applications usually utilize, although very restrictive, the hypothesis of isotropy. Let Z be a SRF which is second order stationary and let C be its covariance function. Then Z is *isotropic* on $\mathbb{R}^n$ ($n \in \mathbb{N}_+$), if there exists a function C_0 such that:

$$C(\mathbf{s}_1 - \mathbf{s}_2) = C_0(\|\mathbf{h}\|), \quad \mathbf{s}_1, \mathbf{s}_2 \in D, \mathbf{s}_1 - \mathbf{s}_2 = \mathbf{h}, \quad (13)$$

where $\|\cdot\|$ indicates the norm in the Euclidean space $\mathbb{R}^n$. Definition (13) can also be given in terms of the variogram.

If C is an isotropic covariance function in $\mathbb{R}^n$, then C is also an isotropic covariance function in $\mathbb{R}^m$, with $m < n$; the same property holds for a variogram function γ . However the converse could not be true.

As a consequence, the definition of *anisotropy* stems from the rejection of (13). In Yaglom (1987), some relevant properties concerning the Eq. (13) are described in detail. In classical geostatistics, the class of anisotropic SRF has been often classified in two main subsets, according to two different kinds of anisotropy: geometric anisotropy and zonal anisotropy, which can be equally defined in terms of the covariance or variogram. The first subset includes SRF characterized by a variogram function which presents the same sill value in all directions, but the range changes with the spatial direction. Hence, given an isotropic covariance function C_0 , it can be transformed to a geometric anisotropic covariance function C through a linear transformation of its lag vector

$\mathbf{h} \in \mathbb{R}^n$, i.e., $C(\mathbf{h}) = C_0(\|\mathbf{A}\mathbf{h}\|)$, where the matrix $\mathbf{A}$ is obtained as the product of a rotation matrix with a scaling parameters diagonal matrix.

On the other hand, according to Journel and Huijbregts (1981), by setting equal to zero some values of the previous diagonal matrix, a *zonal anisotropy* is obtained; hence, zonal anisotropy can be defined as a special case of geometric anisotropy.

A covariance function, characterized by zonal anisotropy, can be obtained through the sum of covariance functions, where each covariance is defined on a proper subspace of the spatial domain. As shown hereafter, the following covariance function in $\mathbb{R}^n$ is given as the sum of the models C_1 and C_2 , i.e.,

$$C(\mathbf{h}) = C_1(\mathbf{h}_1) + C_2(\mathbf{h}_2), \quad \mathbf{h} = (\mathbf{h}_1, \mathbf{h}_2),$$

where $\mathbf{h}_1 \in \mathbb{R}^{n_1}$ and $\mathbf{h}_2 \in \mathbb{R}^{n_2}$, with $\mathbb{R}^n = \mathbb{R}^{n_1} \times \mathbb{R}^{n_2}$.

Zimmerman (1993) introduced a peculiar classification of anisotropy. In particular, he dropped out the definition of “zonal anisotropy” for the more explanatory terms such as “range anisotropy” (also slope anisotropy), “sill anisotropy,” and “nugget anisotropy,” and to save the classical term “geometric anisotropy,” which is interpreted as a special case of range anisotropy.

Separability

Let C be a covariance function on $\mathbb{R}^n$;

- if $C(\mathbf{h}) = C_1(h_1)C_2(h_2) \cdots C_n(h_n)$, and each $C_i: \mathbb{R} \rightarrow \mathbb{R}$ is a covariance function, $i = 1, \dots, n$, then C is *fully separable*;
- if $C(\mathbf{h}) = C_1(\mathbf{h}_1)C_2(\mathbf{h}_2) \cdots C_k(\mathbf{h}_k)$, $k < n$, and each C_i is a covariance function on $\mathbb{R}^{n_i}$, $i = 1, \dots, k$, with $\mathbb{R}^n = \mathbb{R}^{n_1} \times \mathbb{R}^{n_2} \times \cdots \times \mathbb{R}^{n_k}$, then C is *partially separable*.

If a covariance function is fully separable, then it is partially separable, whereas the converse is not true.

Symmetry

Symmetry is a further characteristic of a SRF which is second order stationary; in particular:

- A SRF is *axially symmetric*, if $C(h_1, \dots, h_j, \dots, h_n) = C(-h_1, \dots, h_j, \dots, h_n) = C(h_1, \dots, -h_j, \dots, h_n)$ for a given j . This last property is named *axial or reflection symmetry* in $\mathbb{R}^2$;
- A SRF is *quadrant symmetric*, if $C(h_1, \dots, h_j, \dots, h_n) = C(h_1, \dots, -h_j, \dots, h_n)$ for all $j = 1, \dots, n$.

In particular, in $\mathbb{R}^2$, a SRF is

- *Laterally or diagonally symmetric*, if $C(h_1, h_2) = C(h_2, h_1)$, $(h_1, h_2) \in \mathbb{R}^2$.
- *Complete symmetric*, if both diagonal and reflection symmetric properties are satisfied, i.e., $C(h_1, h_2) = C(-h_1, h_2) = C(h_2, h_1) = C(-h_2, h_1)$, $(h_1, h_2) \in \mathbb{R}^2$.

Note that the set of isotropic covariance functions is a subset of the class of symmetric covariance functions.

Remarks

Symmetry, strict positive definiteness, and separability do not require any form of stationarity for the SRF. On the other hand, the property of isotropy is appropriate only for second order stationary SRFs. A covariance function can be separable and isotropic if and only if all the factors of the product model are Gaussian covariance functions (De Iaco et al. 2020).

Covariance and Variogram Models

Given the difficulties to verify conditions (11) and (12), it is advisable for users to look for the best model of spatial correlation, for a given case study, among the wide parametric families whose members are known to respect the above conditions. Specific details about the construction and characteristics of covariance and variogram models are given in Chiles and Delfiner (1999), Cressie (1993), and Journel and Huijbregts (1981).

Several parametric families of covariance and variogram models can be found in the previous mentioned geostatistical textbooks. Among the various variogram models, the most utilized, such as the *exponential*, the *gaussian*, the *rational quadratic*, and the *power* model, are valid in $\mathbb{R}^n$, $n \geq 1$, whereas the *spherical* model is valid in $\mathbb{R}^n$, with $n \leq 3$. With the exception of the power model which is unbounded, all the previous models are bounded. Spatial correlation with an alternance of positive and negative values, caused by a periodicity of the spatial phenomenon, is often modeled by the *hole effect* or *wave* variogram.

Some isotropic semivariogram models proposed in the literature for a random function that satisfies at least the intrinsic hypotheses are reported below. For simplicity of notation, the semivariogram is assumed to be dependent on the modulus of $\mathbf{h}$, that is $\gamma(\mathbf{h}) = \gamma(h)$, where $h = \|\mathbf{h}\|$.

• Spherical model.

$$\gamma(h) = \begin{cases} C \left[1, 5 \frac{h}{a} - 0, 5 \left(\frac{h}{a} \right)^3 \right] & 0 \leq h \leq a \\ C & h > a \end{cases} \quad (14)$$

where $a \in \mathbb{R}_+$ is the *range* and $C \in \mathbb{R}_+$ is the *sill* value.

• Exponential model.

$$\gamma(h) = C[1 - \exp(-h/a)], \quad (15)$$

where $a \in \mathbb{R}_+$ is the *range* and $C \in \mathbb{R}_+$ is the *sill* value. This model reaches the sill value asymptotically, then the value a' for which $\gamma(a') = 0, 95C$ is such that $a' = 3a$ and it is called *effective range*.

• Gaussian model.

$$\gamma(h) = C[1 - \exp(-h^2/a^2)], \quad (16)$$

where $a \in \mathbb{R}_+$ is the *range* and $C \in \mathbb{R}_+$ is the *sill* value. Similarly to the previous model, it reaches the sill value asymptotically and the value a' for which $\gamma(a') = 0, 95C$ is such that $a' = \sqrt{3}a$.

• Power model.

$$\gamma(h) = \omega h^\alpha, \quad (17)$$

with $\alpha \in [0, 2]$.

This function is concave for $0 < \alpha \leq 1$, while it is convex for $1 < \alpha < 2$.

- **Hole effect model.** The *hole effect* models are used to describe the behavior of a semivariogram which does not grow monotonically, as h increases.

– *Hole Effect 1.*

$$\gamma(h) = C[1 - \cos(h/a)], \quad (18)$$

with $a \in \mathbb{R}_+$ and $C \in \mathbb{R}_+$. This model, valid in $\mathbb{R}$, presents a hole effect, which is described by a periodic component, without damping in the oscillations.

– *Hole Effect 2.*

$$\gamma(h) = C[1 - \exp(-h/a_1) \cos(h/a_2)], \quad (19)$$

with $a_1, a_2 \in \mathbb{R}_+$ and $C \in \mathbb{R}_+$. This model is valid in $\mathbb{R}$; moreover, it is valid in $\mathbb{R}^2$ if and only if $a_2 \geq a_1$ and in $\mathbb{R}^3$ if and only if $a_2 \geq a_1\sqrt{3}$ (Yaglom 1987).

– *Hole Effect 3.*

$$\gamma(h) = C[1 - (a/h) \sin(h/a)], \quad (20)$$

with $a \in \mathbb{R}_+$ and $C \in \mathbb{R}_+$. This model is valid in $\mathbb{R}^3$ and similarly to the previous model presents a damping effect in the oscillations.

Figure 1 shows the semivariogram models analytically described above.

Further classes and specific properties of correlation models, which are constructed through the modified Bessel functions, can be found in Matern (1980).

**Characteristics of Spatial Autocorrelation**

In the present section some characteristics of the variogram functions are briefly discussed, essentially because they are useful to choose an appropriate model of spatial correlation. At this purpose, the behavior near the origin and the behavior for large distances are often relevant issues.

Sill and Range

For what concerns the behavior of a semivariogram for large distances, two typical situations are usually encountered: the semivariogram systematically increases at large distances, otherwise it stabilizes around a particular value, which is called sill, while the corresponding distance at which the sill is reached is called range. In this last case, for distances greater than the range, there is absence of spatial correlation.

Nested Structures

The variogram can reveal nested structures, that is, hierarchical structures, each characterized by its own range (Journel and Huijbregts 1981).

Behavior Near the Origin

The importance of the behavior of a variogram close to the origin is related to the regularity of the spatial variable. In particular, a *parabolic behavior* is typical of a spatial variable which is very regular and the corresponding RF is differentiable in the mean square sense. A *linear behavior* is typical of a spatial variable which is not so regular as in the previous case, while the corresponding RF is continuous but not differentiable in the mean square sense. If the semivariogram presents a discontinuity at the origin, called *nugget effect*, then the spatial variable is very irregular. The denomination

nugget effect originates from the strong variability presented in gold deposits. However, the discontinuity of a variogram at the origin can be caused by several reasons, well described in the classical geostatistical references (Journel and Huijbregts 1981). At last, if the variogram function is a flat curve, then this behavior is typical of absence of spatial correlation.

Hole Effect

If the variogram function presents some bumps for some distances, which correspond to negative values (holes) of the covariance function, then the physical interpretation of this behavior derives from the presence of couples of locations, at the same distances, where relatively low values of the spatial variable are combined with relatively high values and vice versa.

Periodicities

As well known, temporal observations frequently present a periodic behavior, because of the natural influence of cycles which characterize human activities and natural phenomena: this periodic behavior is captured by a correlation measure. On the other hand, spatial variables are rarely characterized by periodicities, except in some peculiar cases, such as the behavior of sedimentary rocks.

Presence of a Drift

If the sample variogram increases faster than a parabola for large distances, then this behavior reflects the presence of a trend in the data, hence the expected value of the SRF cannot be assumed constant over the spatial domain.

Structural Analysis

The whole geostatistical analysis can be summarized through the following steps:

1. Look for a model of the SRF from which data could reasonably be derived.
2. Estimate the variogram as a measure of the spatial correlation exhibited by the data.
3. Fit a suitable model to the estimated variogram.
4. Use this last model in the kriging system for spatial prediction.

In particular, structural analysis is executed on the realizations of a second order stationary SRF. These realizations correspond directly to the observed values (if the macro scale component can be reasonably supposed constant over the domain) or to the residuals otherwise.

Structural analysis begins with the estimation of the semi-variogram or covariogram of the residual SRF Y defined in (2). Given the set $A = \{\mathbf{s}_i, i = 1, 2, \dots, n\}$ of data locations, the semi-variogram can be estimated through the sample semi-variogram $\hat{\gamma}$ as follows:

$$\hat{\gamma}(\mathbf{r}_s) = \frac{1}{2|L(\mathbf{r}_s)|} \sum_{L(\mathbf{r}_s)} [Y(\mathbf{s} + \mathbf{h}) - Y(\mathbf{s})]^2 \quad (21)$$

where $|L(\mathbf{r}_s)|$ is the cardinality of the set $L(\mathbf{r}_s) = \{(\mathbf{s} + \mathbf{h}) \in A, (\mathbf{s}) \in A : \mathbf{h} \in \text{Tot}(\mathbf{r}_s)\}$, and $\text{Tot}(\mathbf{r}_s)$ is a specified tolerance region around $\mathbf{r}_s$. Similarly, the sample covariogram $\hat{C}$ is defined below:

$$\hat{C}(\mathbf{r}_s) = \frac{1}{|L(\mathbf{r}_s)|} \sum_{L(\mathbf{r}_s)} [Y(\mathbf{s} + \mathbf{h}) - \bar{Y}][Y(\mathbf{s}, t) - \bar{Y}], \quad (22)$$

where $\bar{Y}$ is the sample mean.

The second step of structural analysis consists in fitting a theoretical model to the sample spatial semi-variogram or covariogram. As already underlined in one of the previous sections, various classes of covariance functions or semi-variograms are available. Variogram or covariogram modeling has been a research focus in this field for a long-time. Maximum likelihood and least squares are the two common ways to achieve this model fitting goal. Some details on the fitting aspects can be found in Cressie (1993).

After modeling the spatial empirical variogram/covariogram surface, the subsequent step is to evaluate the reliability of the fitted model through the application of cross-validation and jackknife techniques. Then, if the model performance is satisfactory, the same model can be used to predict the variable under study over the spatial domain by using kriging.

Through the cross-validation technique all the observed values are removed, one at a time, and at each location where the observed value has been temporarily removed, the spatial variable is estimated by utilizing all the remaining observed values and the selected variogram model. At last, the estimated values are compared with the observed ones through the correlation coefficient. On the other hand, the technique of jackknife operates in a different way; in particular, two different data sets of observed values are considered. The first data set is the one used in structural analysis to estimate and model the correlation function (variogram); this last model is then used to predict the spatial variable at the locations of the second data set. Hence, these last estimated values are compared with the true values (which are known) of the second data set, called for this reason, control data set.

From a computational point of view, the literature offers various packages which perform structural analysis in two and three dimensions, such as the Geostatistical Software Library GSLIB and its version for Windows WinGSLIB (Deutsch and Journel 1998), SGeMS (Remy et al. 2009), as well as the commercial software ISATIS. Moreover, in the R environment, there are various packages devoted to geostatistical modeling, such as gstat and RGeostats (Pebesma and Wesseling 1998; Renard et al. 2014).

Multiple Point Statistics

As previously pointed out, the analysis of spatial correlation in classical geostatistics is based on the variogram or covariance function. However, these tools, which are known as two point statistics, could not be appropriate for modeling phenomena which present curvilinear structures or, more generally, complex spatial patterns. At this purpose, multiple point statistics (Krishnan and Journel 2003) represent a solution to overcome these difficulties since the relations among the variables at more than two points at a time are considered. Unfortunately, spatial data are usually sparse, hence they are not very informative for the application of multiple point statistic techniques. These last problems can be overcome by utilizing training images from which multiple point statistics can be provided.

Complex Random Functions

Complex RFs, as a generalization of real RFs, can be useful to model vectorial data in $\mathbb{R}^2$: for example, a wind field can be viewed as a complex variable by considering the intensity of the wind speed and its direction at each spatial location (De Iaco and Posa 2016). Let $\mathbb{R}^n$ and $\mathbb{C}$ be the n -dimensional Euclidean space and the set of complex numbers, respectively. Let Z_1 and Z_2 be the real components of the following complex RF Z :

$$Z(\mathbf{s}) = Z_1(\mathbf{s}) + iZ_2(\mathbf{s}), \mathbf{s} \in \mathbb{R}^n,$$

where $i^2 = -1$, with i the imaginary unit.

If Z is a second order stationary RF, its covariance function is defined as follows:

$$C(\mathbf{h}) = E[(Z(\mathbf{s}) - m)\overline{(Z(\mathbf{s} + \mathbf{h}) - m)}]$$

and it can be expressed in the following form: $C(\mathbf{h}) = C_{re}(-\mathbf{h}) + iC_{im}(\mathbf{h})$, where

$$C_{re}(\mathbf{h}) = C_{Z_1}(\mathbf{h}) + C_{Z_2}(\mathbf{h}), C_{im}(\mathbf{h}) = C_{Z_2Z_1}(\mathbf{h}) - C_{Z_1Z_2}(\mathbf{h})$$

C_{re} is an even function and it is a real covariance function, whereas C_{im} is an odd function and it is not a covariance function.

Note that the following properties generalize the previous ones given in (10) for a real valued covariance function: $C(-\mathbf{h}) = \overline{C(\mathbf{h})}$; $C(\mathbf{0}) \geq 0$; $|C(\mathbf{h})| \leq C(\mathbf{0})$.

The theorem of Bochner (1959) specifies that any continuous covariance function can be represented as follows:

$$C(\mathbf{h}) = \int_{\mathbb{R}^n} \exp(i\boldsymbol{\omega}^T \mathbf{h}) dF(\boldsymbol{\omega}), \quad (23)$$

where F is a non-negative and finite measure on $\mathbb{R}^n$. Hence, according to the previous theorem, a covariance is a complex valued function.

A detailed discussion on the construction of complex and, in particular, of real covariance functions has been recently given in Posa (2020). In particular, the symmetry of the spectral distribution function or the property of the spectral density function to be an even function, guarantee that the covariance is a real function. Otherwise the covariance is a complex function.

Summary and New Results

In the present section, a summary on spatial autocorrelation, as well as some recent and significant results will be provided.

- One of the main issues, which often requires a specific answer, concerns the measure of spatial autocorrelation to be utilized for the case study at hand. Indeed, the answer to this kind of question is not so easy, as could appear or as often underlined in the literature. In fact, in most of the geostatistical applications the variogram is preferred to the covariance function, essentially because the first function satisfies the intrinsic hypotheses, which describe a wider class of spatial RFs respect to the processes which satisfy the hypotheses of second order stationarity. Several papers provide a comparison between these two correlation functions and the above choice is often justified by further reasons (Cressie and Grondona 1992).
- On the other hand, the variogram, by definition, is a variance, hence it is a real valued function; according to Bochner's theorem, the covariance is a complex valued function and it is suitable to analyze vectorial data in two dimensions, as shown in some interesting applications concerning phenomena which often happen in oceanography, environmental and ecological sciences, geophysics, in meteorology, and signal analysis.
- If the spatial variable is a scalar quantity, the variogram or, more generally, the formalism of the IRFk could be a suitable choice for the measure of spatial autocorrelation.
- In presence of curvilinear or complex spatial patterns, if a training image is available, then the techniques of multiple point statistics are recommended, as shown in several applications.
- Wide classes of parametric families of complex covariance functions have been recently constructed (Posa 2020). These complex covariance models could be applied in a spatial context, in several dimensional spaces, as well as in

a spatiotemporal domain to model the correlation structure of complex valued random fields.

- Although it is well known that the difference of two covariance functions could not be a covariance function, several classes of models for the difference of two covariance functions have been recently constructed in the complex domain and in the subset of the real domain (Posa 2021). All the relevant issues and consequences which stem from this last result are also discussed in the same paper.

Definition

Data which present a spatial component are called spatial data (Fischer and Wang 2011). In a nutshell, they are sample data of a random field referred to a spatial domain.

Overview

Spatial data are a collection of observations measured in different locations on a spatial domain. They are interpreted as a finite realization of a random field, whose distribution law (often unknown) provides a likelihood measure of the spatial evolution of the phenomena under study.

Spatial data have two characteristics, that is:

- They are non-repetitive, since only one observation is available in every single location.
- They are spatially correlated, which means that the phenomenon under study varies in space, but the variations are correlated over some distances.

For this last reason, the usual assumption of independence, made in classical statistical inference, is not reasonable in

Spatial Data, Table 1 Classification and characteristics of spatial data, together with the R packages available for their analysis

spatial statistics. Indeed spatial data usually show dependencies along any direction in the domain, and their intensity is generally closely connected with the distance between locations and weakens as the distance arises (Cressie 1993). This feature of the spatial data recalls Tobler's first law of geography: "everything is related to everything else, but near things are more related than distant things" (Tobler 1970).

Spatial data are used in various scientific fields, such as agriculture, geology, environmental sciences, hydrology, epidemiology, and economics (Müller 2007). In the geographical information system, the term spatial data is used to refer to features (points, lines, and polygons) linked to a geographic location on the Earth; in this sense, the features are georeferenced. Note that each specific application often requires an appropriate data resolution, since some features of interest are scale-dependent (Flury et al. 2021).

Types of Spatial Data

Over the past 40 years, many studies have been carried out on spatial data analysis considered from different points of view (Ripley 1981; Isaaks and Srivastava 1989; Goovaerts 1997; Chilès and Delfiner 2012; Schabenberger and Gotway 2005 and others).

Given a spatial random field in a d -dimensional space $\{Z(\mathbf{s}) : \mathbf{s} \in D \subset \mathbb{R}^d\}$, where $Z(\mathbf{s})$ denotes a spatial random variable and $\mathbf{s}$ a location of the spatial domain D , the spatial data can be classified with respect to the nature of the domain D , as follows:

- Geostatistical data
- Lattice data
- Point patterns

A summary of these spatial data classification is provided in Table 1. For further details on the spatial data classification, the readers may refer to Cressie (1993).

Geostatistical Data

In the case of geostatistical data, the sample data are considered as a finite realization of the random field $\{Z(\mathbf{s}) : \mathbf{s} \in D\}$. The values that can be observed at the i -th spatial point is interpreted as a possible realization of a random variable, which is denoted as $Z(\mathbf{s}_i)$, where $\mathbf{s}_i$ represents the spatial location (Cressie 1993). Moreover, the peculiar feature of geostatistical data is that the domain $D \subset \mathbb{R}^d$ is continuous and fixed. If $d = 2$, the spatial location $\mathbf{s}$ is characterized by the Cartesian coordinates (x, y) . In this field of spatial data, the locations are treated as explanatory variables and the values recorded at these locations as response variables.

The spatial domain is continuous since the random variable $Z(\mathbf{s})$ can be observed at any point of D ; hence between two spatial locations $\mathbf{s}_i$ and $\mathbf{s}_j$, an infinite/non-countable number of other spatial locations can be fixed. It is worth noting that the adjective continuous refers to the spatial domain and not to the type of the random variable measured on it, which could be continuous or discrete.

Furthermore, the spatial domain is fixed in the sense that the spatial points $\mathbf{s}_i$, $i = 1, \dots, n$, are non-random (Schabenberger and Gotway 2005; Cressie 1993).

It is important to highlight that since the spatial domain is continuous, it cannot be sampled totally; consequently, the sample data is sampled at a finite number of locations, chosen at random or by a deterministic method. The sampling design takes into account sampling costs, benefits, and experimental constraints (i.e., locations of measuring stations).

Spatial Data, Fig. 1 (a) Gray scale map and (b) contour map of the soil clay percentage in an Italian district (Source data: soil map of Italy, year 2000, <https://esdac.jrc.ec.europa.eu/>)

Since there are only few measurements of the phenomena under study over the spatial domain, in geostatistics the main objective is the estimation of the random variable $Z(\mathbf{s})$ at unsampled spatial location, starting from observations available at a finite set of locations. The kriging is the most and widely used method for predicting the random variable in an unsampled location, by means of the observed data. This optimal prediction method requires the knowledge of a variogram/covariogram model, for this reason a relevant effort is devoted to estimate the spatial correlation function (through the variogram or the covariogram) as well as to fit a model to it.

In the following, an example regarding geostatistical data is proposed.

Example 1 Soil clay content is a key parameter in soil science, since it influences magnitudes and rates of several chemical, physical, and hydrological phenomena in soils. Given a spatial sampling, the observations of this feature taken at the sampled spatial locations can be considered as geostatistical data. Indeed, the soil clay content can be evaluated at any location of a given domain D , but only few measurements at some spatial locations are available. One of the main goals might be to define a continuous surface across the domain in order to estimate the spatial variability of the soil clay content over the area under study.

In Fig. 1, a location map of 485 sample points regarding the soil clay percentage in an Italian district and the corresponding kriging estimates, over the entire domain, are shown (Posa and De Iaco 2009). The estimates are obtained by using the ordinary kriging method and a variogram model.

Lattice Data

Lattice data are spatial data where the domain D is a countable collection of spatial regions at which the random variable is observed. The spatial regions are such that none of them can intersect each other, and the regions are characterized by a neighborhood structure. For example, in a 2D space, the spatial domain can be expressed as the set of the areas A_i , $i = 1, \dots, n$, which cover the territory under study D :

$$D = \{A_1, A_2, \dots, A_n\} \quad A_i \subset D \subset \mathbb{R}^2 \quad A_1 \cup A_2 \cup \dots \cup A_n = D$$

with $A_i \cap A_j = \emptyset$, $i, j \in \mathbb{N}_+$, $i \neq j$.

Hence, in this context, the spatial domain is fixed and discrete. In particular, the spatial domain is

- Fixed, in the sense that the spatial regions A_i , $i = 1, \dots, n$, in D are not stochastic (Schabenberger and Gotway 2005).
- Discrete, since the number of spatial regions could be infinite, although countable.

The spatial data could refer to a regular lattice (i.e., the cells/regions show the same form and size) or irregular lattice (i.e., the spatial domain is divided into cells/regions according to the natural or policy barriers). Moreover, the data do not correspond to a specific point in space, but to the entire region. Thus, it is usually assigned to each area a representative location in space, which is usually the centroid of the region, and then recorded for each centroid the corresponding spatial coordinates (i.e., longitude and latitude) in a 2D domain. Therefore, the spatial domain can be also formalized as follows:

$$D = \{(i; x_i, y_i) : i = 1, \dots, n\}$$

where i denotes the i -th region under study, x_i and y_i are the longitude and latitude of the i -th centroid, respectively.

Similarly to the geostatistical context, the values that can be observed at the i -th region are interpreted as a possible realization of a random variable, which is denoted as $Z(\mathbf{s}_i)$, where $\mathbf{s}_i$ represents the centroid of the corresponding region and refers to the representative location (Cressie 1993). In other contributions (see, for example, Schabenberger and Gotway 2005), the notation $Z(A_i)$ is used, in order to underline the areal nature of lattice data, where A_i is the i -th sampled areal unit.

It is important to point out that a specific feature of the lattice data is that they are exhaustive over the spatial domain. Moreover, they usually concern aggregated data over the sample region. However, the aggregation of the data causes sometimes some problems; in particular if the level of aggregation is chosen arbitrarily, the *modifiable areal unit problem* can arise (Openshaw and Taylor 1979), since the size of the areas on which aggregation is applied influences the correlation between variables. This problem occurs frequently in ecology, where most of ecological variables depend on other covariates, acting at different spatial scales (Saveliev et al. 2007).

Note that, in the analysis of the lattice data, the estimation of the random variable at unsampled points is not relevant, since the phenomenon under study is known over the entire domain, but the main goal is to model the spatial process using the spatial regression method. In the model, the variable of interest is predicted by using other variables measured on the same areas as well as by including the spatial dependence of neighboring regions, since if regions are nearby, the random variables collected at these areas could be spatially correlated.

In order to include the spatial component in the regression model, the covariance structure must be identified. This last requires to define previously a neighborhood structure by means of the $(n \times n)$ spatial weights matrix $\mathbf{W}$, whose elements w_{ij} are defined as follows:

$$w_{ij} = \begin{cases} 1 & \text{if } A_i \text{ and } A_j \text{ share a common border,} \\ 0 & \text{otherwise.} \end{cases} \quad (1)$$

Note that symmetry of the weights is not a requirement (Schabenberger and Gotway 2005). Regions which are neighboring and with similar values identify a spatial pattern, which is representative of a cluster, and the selection of correlated variables with the one of interest helps in the detection of explicative factors for the analyzed phenomenon.

For lattice data modeling, the wider applied approaches are based on the linear regression models. However, if the residuals highlight the presence of spatial correlation, alternative models which take into account the spatial dependence could be used. Among these, it is worth mentioning the conditional spatial autoregression (CAR), simultaneous spatial autoregression (SAR), and moving average (MA) models.

In the following, an example regarding lattice data is proposed.

Example 2 The total fertility rate (TFR) is the average number of children that a woman would potentially have in her child-bearing years (i.e., for ages 15–49).

In Fig. 2, the map of the centroids of the regions and the color map of this demographic index, available for each region in France, are provided (De Iaco et al. 2015). This is a typical example of lattice data, where the domain D is a set of 21 counties; thus it is fixed and discrete. Moreover, the TFR is an aggregate statistic over each region.

Point Patterns

Geostatistical and lattice data are measured over a fixed, non-stochastic domain, where the term “fixed” is used to highlight that the domain D does not change if different realizations of the spatial process are considered. Moreover, for these types of data, the analyst is interested in the measurement of the attribute Z over the spatial domain D . On the other hand, if the analyst intends to focus only on the location at which an event occurs, such a dataset is known as spatial point pattern.

Diggle (2003) defined the point process as a “stochastic mechanism which generates a countable set of events,” where the events are the points of the spatial pattern in a bounded region. The point patterns are said to be *sampled* or *mapped*, if the events are partially observed or if all the events are recorded, respectively.

For a spatial point process, the spatial domain D is a collection of points on the hyperplane

$$D = \{\mathbf{s}_1, \mathbf{s}_2, \dots, \mathbf{s}_n\}$$

Spatial Data, Fig. 2 (a) Location map of the regional centroids and (b) color map of the yearly TFR registered in 2011 for the 21 regions of mainland France (Source data: Eurostat, 2013, <http://epp.eurostat.ec.europa.eu/portal/page/portal/statistics>)

In general, no random variable $Z(\mathbf{s})$ is observed at these points. Otherwise, if an attribute is measured in each point, the realization of a point process $\{Z(\mathbf{s}) : \mathbf{s} \in D \subset \mathbb{R}^d\}$ represents a pattern of points over the domain D . In order to distinguish these two cases, in the literature the terms *unmarked* and *marked* point pattern are often used. In particular, the former is given to the locations where the event occurs, while the latter is used when an attribute $Z(\cdot)$ is also observed at these points. For instance, the locations at which trees emerge in a forest, the spatial distribution of schools in a city, or the locations of an earthquake are examples of unmarked point patterns. Nevertheless, the set of locations regarding the height of trees in a forest, the size of schools in a city, or the magnitude of earthquakes are examples of marked point patterns.

It is important to highlight that, in contrast with geostatistical and lattice data, which can be measured at any point of the spatial domain D , a point process takes nonzero values only in specific points that are the ones in which the underlying process occurs (Hristopulos 2020). Moreover, in spatial point pattern statistics, the spatial locations as well as the values measured in each point are treated as response variables.

Given a random set D , for each region $A_i \in D$, $N(A_i)$ denotes the number of points in the region A_i and $\lambda(A_i)$ is the average number of events in the same area. The point pattern is named *completely random process* or, alternatively, *Poisson point process* if the following properties are satisfied:

- The intensity function $\lambda(\cdot)$, which is the average number of points in each area, is constant.
- The numbers of events in two areas A_i and A_j , such as $A_i \cap A_j = \emptyset$, $i, j \in \mathbb{N}_+$, $i \neq j$, in the domain D are

independent; hence the probability that an event occurs is equal in each spatial location.

Note that this model is widely used in spatial point pattern analysis, to compare the locations of the events with this reference distribution. However, the Poisson point process does not always adequately describe phenomena with spatial clustering of points and spatial regularity. In the literature, a variety of other models were proposed, among these the Cox process, the inhibition process, or the Markov point process (Cressie 1993; Schabenberger and Gotway 2005).

The objectives of point pattern analysis vary according to the scientist's purposes. In general, it is relevant to focus on the spatial distribution of the observed events and make inference about the underlying process that generates them. In particular, it could be interesting to analyze the distribution of the points in space, in terms of intensity of the point pattern, as well as the existence of possible interactions between events, which may reveal the tendency of events to appear clustered, independently, or regularly spaced (Bivand et al. 2013). For example in ecology, a target could be determining the spatial distribution of a tree species over a study area or assessing whether two or more species are equally distributed. Furthermore, in spatial epidemiology, it could be challenging to check whether or not the cases of a certain disease are clustered. This approach can be also used in human sciences, to identify, for example, areas where crimes occur, the activity spaces of individuals, the catchment areas of services, such as banks and restaurants.

In the following, an example regarding point patterns is proposed.

Example 3 In Fig. 3, a map of bicycle theft crimes occurring in London (September 2017) is shown. This represents an

Spatial Data, Fig. 3 Location map of bicycle thefts in the city of London in September 2017 (Source data: UK Police Department 2017, <https://data.police.uk/data/archive/>)

example of unmarked spatial point pattern, which consists of 2218 locations of bicycle thefts recorded within the city of London.

Summary

The spatial data include information on the location and the measured attributes. They have two fundamental characteristics: (a) dependency between specific locations along any direction, where the intensity becomes weaker as the distance arises, and (b) non-repetitive, since only one observation is available in every single location.

As reported in Cressie (1993), the spatial data types have been classified with respect to the characteristics of the domain D , as geostatistical data, lattice data, and point patterns.

Spatial Data Infrastructure and Generalization

Jagadish Boodala, Onkar Dikshit and
Nagarajan Balasubramanian
Department of Civil Engineering, Indian Institute of
Technology Kanpur, Kanpur, UP, India

Definition

The Spatial Data Infrastructure (SDI) is a framework that facilitates the reuse and integration of spatial data and services available from different sources. SDI framework is a collection of policies, spatial data, technologies, humans, and institutional arrangements that ease the sharing and reuse of spatial data. The main component of SDI is spatial data. The

generalization plays an essential role in situations where the spatial data of different levels of detail or scales are to be combined and made homogeneous. The transformation of spatial data from more detailed to the abstract level of detail is called generalization.

Introduction

Traditional maps were the outcome of spatial observations for many years to get the spatial context (Tóth et al. 2012). With technological advancements, conventional paper maps were replaced by digital spatial data. Initially, the public sector was responsible for capturing and producing a significant portion of the spatial data, such as National Mapping and Cadastral Agencies (Toomanian 2012). The private sector has shown interest in the spatial data when its applications have increased in areas like location-based services, agriculture, intelligent navigation, etc. The licensing issues of authoritative spatial data from public and private sectors lead to the

crowdsourced data called volunteered geographic information (Toomanian 2012).

The availability of spatial data from the public, private, and crowdsourced have resulted in the data explosion. Furthermore, the number of spatial data processing tools has also increased. The cost of data capturing is high; hence there is a necessity to reuse the existing spatial data. There is a need for a framework, called SDI, to make better sense and use of the current spatial data. One such legal framework to establish European SDI is INSPIRE. INSPIRE stands for the Infrastructure for Spatial Information in the European Community. INSPIRE's main objective is to assist in policy-making related to environmental issues by improving the accessibility and interoperability of spatial data among European Union member states (Duchêne et al. 2014; INSPIRE 2007a).

As the spatial data are coming from various sources, there is a possibility that the same real-world phenomena are modeled and represented by different viewpoints and also at different levels of detail or scales. The multiple representations are quite common, which can be derived and handled by a generalization process (Tóth 2007). The following sections

Spatial Data Infrastructure and Generalization, Fig. 1 Features of different themes at the same level of detail. (Contains OS data © Crown copyright and database right (2017))

highlight the requirements set out by the INSPIRE Directive (INSPIRE 2007a) to achieve data interoperability and explain how generalization can help in achieving it.

INSPIRE: Multiple Representations and Data Consistency

The possibility of combining spatial data sets, without repetitive human intervention, into coherent data sets whose value is enhanced is called data interoperability (INSPIRE 2007a). Recital 6 of the INSPIRE Directive provides five common principles of INSPIRE (INSPIRE 2007a, b). The first three principles form the basis for defining data interoperability (INSPIRE 2014).

Article 8(3) and Article 10(2) of the INSPIRE Directive provide the requirements to handle multiple representations and data consistency (INSPIRE 2007a). Hence, the elements “(Q) Consistency between data,” and “(R) Multiple representations” are included as the data interoperability components (INSPIRE 2014).

The component “(Q) Consistency between data” provides the rules to maintain consistency between the data corresponding to the same location or between the same data collected at different levels of detail or scales (INSPIRE 2007a). However, the component “(R) Multiple representations” explains how generalization can be used to derive multiple representations (INSPIRE 2014). Another data interoperability component that specifies the target scale range is the element “(S) Data capturing.” This component defines the data capturing rules or selection criteria according to the target scale (INSPIRE 2014).

The requirements of INSPIRE discussed above helps to pinpoint the situations where generalization finds its worth.

Generalization in the Context of INSPIRE

The first principle of INSPIRE (INSPIRE 2007b), “data should be collected only once,” motivates to apply an automatic generalization to derive spatial data of abstract levels of

Spatial Data Infrastructure and Generalization, Fig. 2 Building features at two different levels of detail. (Contains OS data © Crown copyright and database right (2017))

detail. These different representations of the same real-world phenomena are called multiple representations.

The generalization is a process of reducing the level of detail or scale of the spatial data by applying a broad set of operators called generalization operators. The high-level classification of generalization operators is either based on automation (Foerster et al. 2007) or the cartographer's (Roth et al. 2011) point of view. However, the essential list of generalization operators includes selection, simplification, classification, collapse, merge, typification, displacement, enhancement, and elimination. The data capturing rules, for example, minimum area or length, defined in INSPIRE, are useful while performing the selection operation.

The generalization is a complex process. It is challenging to achieve unique results because of the subjectivity involved in the process itself (Stoter 2005). The issues with generalization are its subjectivity, complexity, and immaturity. Hence, generalization service is not part of the INSPIRE data transformation services; however, multiple representations are allowed in INSPIRE (INSPIRE 2008).

The modeling of multiple representations in INSPIRE paves the way for easy integration of spatial data sets from

different sources. While dealing with multiple representations and data sets from different sources, it is necessary to maintain consistency between the datasets. INSPIRE identifies different types of consistency checks: within a data set, between features of different themes at the same level of detail, and between the same feature at different levels of detail (INSPIRE 2014).

Figure 1 shows the scenario where the features of different themes are represented together in a product of scale 1:10000. The generalization process should consider the consistency rules defined between all the features. These rules are developed based on logical, functional, and geometrical relationships between features. For example, Building features must not overlap between themselves and with the Woodland features. The consistency rules are expressed as topological constraints to avoid inconsistencies in the data set and guide the generalization process. The "OS OpenMap – Local" product of Ordnance Survey, UK, is used for the illustration in Fig. 1.

The consistency between multiple representations of the same feature at different levels of detail should be maintained. Fig. 2 explains the importance of this consistency

Spatial Data Infrastructure and Generalization, Fig. 3 Road features at two different levels of detail. (Contains OS data © Crown copyright and database right (2017 & 2015))

requirement. It shows the two representations of the Building features in products of 1:10000 (OS OpenMap – Local) and 1:25000 (OS VectorMap District) scales. The advantages of automatic generalization are twofold. One is in deriving the abstract representations, and the other is in deriving the consistent data sets. Maintaining links between multiple representations from existing data sets is quite challenging than maintaining it between the representations derived via automatic generalization. The established links help in maintaining data consistency (INSPIRE 2008).

Figure 3 illustrates the situation frequently encountered in SDI. It considers the Road features from products of 1:10000 (OS OpenMap – Local) and 1:250000 (Strategi) scales. In this case, the spatial data user has two different data sets of different levels of detail or scales separately covering the region of his/her interest. It is clear from Fig. 3 that the spatial data sets covering the region of the user's interest are heterogeneous. In such cases, generalization comes into the picture to homogenize the level of the detail or scale of the combined spatial data set.

Summary

An increase in spatial data applications in various fields attracted investments in spatial data capturing from both the public and private sectors. Nevertheless, the data capturing cost remains high. Some policies or decisions, for example, related to the environment or disaster management, have to be taken at the national or international level. In such cases, spatial data from different sources are required to support the policy or decision-making. The spatial data from different sources cannot be integrated and used instantaneously because of different standards followed in capturing it. Also, the accessibility of the spatial data sets is not easy and quick. All these aspects lead to the SDI, and the INSPIRE Directive aims to establish a European Union SDI. The spatial data is an essential component of INSPIRE, and for that matter, of any SDI. Hence, INSPIRE defines a total of 20 elements as the data interoperability components. Among those 20 elements, generalization finds its application in only 3 components to achieve data interoperability. They are “(Q) Consistency between data,” “(R) Multiple representations,” and “(S) Data capturing.” In the future, generalization can be used in INSPIRE view services to provide high-quality cartographic data in an INSPIRE geportal.

Spatial Statistics

Noel Cressie and Matthew T. Moores
School of Mathematics and Applied Statistics, University of Wollongong, Wollongong, NSW, Australia

Definition

Spatial statistics is an area of study devoted to the statistical analysis of data that have a spatial label associated with them. Geographers often refer to the “location information” associated with the “attribute information,” whose study defines a research area called “spatial analysis.” Many of the ways to manipulate spatial data are driven by algorithms with no

uncertainty quantification associated with them. When a spatial analysis is statistical, that is, when it incorporates uncertainty quantification, it falls in the research area called spatial statistics. The primary feature of spatial statistical models is that nearby attribute values are more statistically dependent than distant attribute values; this is a paraphrasing of what is sometimes called the First Law of Geography (Tobler 1970).

Introduction

Spatial statistics provides a probabilistic framework for giving answers to those scientific questions where spatial-location information is present in the data, and that information is relevant to the questions being asked. The role of probability theory in (spatial) statistics is to model the uncertainty, both in the scientific theory behind the question, and in the (spatial) data coming from measurements of the (spatial) process that is a representation of the scientific theory.

In spatial statistics, uncertainty in the scientific theory is expressed probabilistically through a spatial stochastic process, which can be written most generally as:

$$\{Y(\mathbf{s}) : \mathbf{s} \in \mathcal{D}\}, \quad (1)$$

where $Y(\mathbf{s})$ is the random attribute value at location $\mathbf{s}$, and $\mathcal{D}$ is a subset of a d -dimensional space, for illustration Euclidean space $\mathbb{R}^d$, that indexes all possible spatial locations of interest. Contained within $\mathcal{D}$ is a (possibly random) set D that indexes those parts of $\mathcal{D}$ relevant to the scientific study. We shall see below that D can have different set properties, depending upon whether the spatial process is a geostatistical process, a lattice process, or a point process.

It is convenient to express the joint probability model defined by random $\{Y(\mathbf{s}) : \mathbf{s} \in D\}$ and random D in the following shorthand, $[Y, D]$, which we refer to as the spatial process model. Now,

$$[Y, D] = [Y|D][D], \quad (2)$$

where for generic random quantities A and B , their joint probability measure is denoted by $[A, B]$; the conditional probability measure of A given B is denoted by $[A|B]$; and the marginal probability measure of B is denoted by $[B]$. In this review of spatial statistics, expression (2) formalizes the general definition of a spatial statistical model given in Cressie (1993, Section 1.1).

The model (2) covers the three principal spatial statistical areas according to three different assumptions about $[D]$, which leads to three different types of spatial stochastic process, $[Y|D]$; these are described further in the next section “Spatial Process Models”. Spatial statistics has, in the past, classified its methodology according to the types of spatial

data, denoted here as $\mathbf{Z}$ (e.g., Ripley 1981; Upton and Fingleton 1985; and Cressie 1993), rather than the types of spatial processes Y that underly the spatial data.

In this review, we classify our spatial-statistical modeling choices according to the *process model* (2). Then the *data model*, namely, the distribution of the data $\mathbf{Z}$ given both Y and D in (2), is the straightforward conditional-probability measure,

$$[\mathbf{Z}|Y, D]. \quad (3)$$

For example, the spatial data $\mathbf{Z}$ could be the vector $(Z(\mathbf{s}_1), \dots, Z(\mathbf{s}_n))'$, of imperfect measurements of Y taken at given spatial locations $\{\mathbf{s}_1, \dots, \mathbf{s}_n\} \subset D$, where the data are assumed to be *conditionally independent*. That is, the data model is

$$[\mathbf{Z}|Y, D] = \prod_{i=1}^n [Z(\mathbf{s}_i)|Y, D]. \quad (4)$$

Notice that while (4) is based on conditional independence, the *marginal* distribution, $[\mathbf{Z}|D]$, does *not* exhibit independence: The spatial-statistical dependence in $\mathbf{Z}$, articulated in the First Law of Geography that was discussed in section “Definition”, is inherited from $[Y|D]$ and (4) as follows:

$$[\mathbf{Z}|D] = \int [\mathbf{Z}|Y, D][Y|D]dY.$$

Another example is where the randomness is in D but not in Y . If D is a spatial point process (a special case of a random set), then the data $\mathbf{Z} = \{N, \mathbf{s}_1, \dots, \mathbf{s}_N\}$, where N is the random number of points in the now-bounded region $\mathcal{D}$, and $D = \{\mathbf{s}_1, \dots, \mathbf{s}_N\}$ are the random locations of the points. If there are measurements (sometimes called “marks”) $\{Z(\mathbf{s}_1), \dots, Z(\mathbf{s}_N)\}$ associated with the random points in D , these should be included within $\mathbf{Z}$. That is,

$$\mathbf{Z} = \{N, (\mathbf{s}_1, Z(\mathbf{s}_1)), \dots, (\mathbf{s}_N, Z(\mathbf{s}_N))\}. \quad (5)$$

This description of spatial statistics given by (2) and (3) captures the (known) uncertainty in the scientific problem being addressed, namely, *scientific uncertainty* through the spatial process model (2) and *measurement uncertainty* through the data model (3). Together, (2) and (3) define a *hierarchical statistical model*, here for spatial data, although this hierarchical formulation through the conditional probability distributions, $[\mathbf{Z}|Y, D]$, $[Y|D]$, and $[D]$ for general Y and D , is appropriate throughout all of applied statistics.

It is implicit in (2) and (3) that any parameters θ associated with the process model and the data model are known. We now discuss how to handle parameter uncertainty in the hierarchical statistical model. A Bayesian would put a

probability distribution on θ : Let $[\theta]$ denote the parameter model (or prior) that captures parameter uncertainty. Then, using obvious notation, all the uncertainty in the problem is expressed through the joint probability measure,

$$[\mathbf{Z}, Y, D, \theta] = [\mathbf{Z}, Y, D | \theta][\theta] \quad (6)$$

$$= [\mathbf{Z} | Y, D, \theta][Y | D, \theta][D | \theta][\theta]. \quad (7)$$

A *Bayesian hierarchical model* uses the decomposition (7), but there is also an *empirical hierarchical model* that substitutes a point estimate $\hat{\theta}$ of θ into the first factor on the right-hand side of (6), resulting in its being written as,

$$[\mathbf{Z}, Y, D | \hat{\theta}] = [\mathbf{Z} | Y, D, \hat{\theta}][Y | D, \hat{\theta}][D | \hat{\theta}]. \quad (8)$$

Finding efficient estimators of θ from the spatial data $\mathbf{Z}$ is an important problem in spatial statistics, but in this review we emphasize the problem of spatial prediction of Y . In what follows, we shall assume that the parameters are either known or have been estimated. Hence, for convenience, we can drop $\hat{\theta}$ in (8) and express the uncertainty in the problem through the joint probability measure,

$$[\mathbf{Z}, Y, D] = [\mathbf{Z} | Y, D][Y | D][D], \quad (9)$$

and Bayes' Rule can be used to infer the unknowns Y and D through the *predictive distribution*:

$$[Y, D | \mathbf{Z}] = \frac{[\mathbf{Z} | Y, D][Y | D][D]}{[\mathbf{Z}]}; \quad (10)$$

here $[\mathbf{Z}]$ is the normalization constant that ensures that the right-hand side of (10) integrates or sums to 1. If the spatial index set D is *fixed and known* then we can drop D from (10), and Bayes' Rule simplifies to:

$$[Y | \mathbf{Z}] = \frac{[\mathbf{Z} | Y][Y]}{[\mathbf{Z}]}, \quad (11)$$

which is the *predictive distribution* of Y (when D is fixed and known). It is this expression that is often used in spatial statistics for prediction. For example, the well-known *simple kriging predictor* can easily be identified as the predictive mean of (11) under Gaussian distributional assumptions for both (2) and (3) (Cressie and Wikle 2011, pp. 139–141).

Our review of spatial statistics starts with a presentation in the next section “[Spatial Process Models](#)”, of a number of commonly used spatial process models, which includes multivariate models. Following that, the section “[Spatial Discretization](#)”, turns attention to discretization of $\mathcal{D} \subset \mathbb{R}^d$, which is an extremely important consideration when actually computing the predictive distribution (10) or (11). The

extension of spatial process models to spatiotemporal process models is discussed in the section “[Spatiotemporal Processes](#)”. Finally, in the section “[Conclusion](#)”, we briefly discuss important recent research topics in spatial statistics, but due to a lack of space we are unable to present them in full. It will be interesting to see 10 years from now, how these topics will have evolved.

Spatial Process Models

In this section, we set out various ways that the probability distributions $[Y | D]$, $[Y]$, and $[D]$, given in Bayes' Rule (10), can be represented in the spatial context. These are not to be confused with $[\mathbf{Z} | D]$ and $[\mathbf{Z}]$, the probability distributions of the spatial data. In many parts of the spatial-statistics literature, this confusion is noticeable when researchers build models directly for $[\mathbf{Z} | D]$. Taking a hierarchical approach, we capture knowledge of the scientific process starting with the statistical models, $[Y | D]$ and $[D]$, and then we model the measurement errors and missing data through $[\mathbf{Z} | Y, D]$. Finally, Bayes' Rule (10) allows inference on the unknowns Y and D through the predictive distribution, $[Y, D | \mathbf{Z}]$.

We present three types of spatial process models, where their distinction is made according to the index set D of all spatial locations at which the process Y is defined. For a *geostatistical process*, $D = D^G$, which is a known set over which the locations vary continuously and whose area (or volume) is >0 . For a *lattice process*, $D = D^L$, which is a known set whose locations vary discretely and the number of locations is countable; note that the area of D^L is equal to zero. For a *point process*, $D = D^P$, which is a random set made up of random points in $\mathcal{D}$.

Geostatistical Processes

In this section, we assume that the spatial locations D are given by D^G , where D^G is known. Hence D can be dropped from any of the probability distributions in (10), resulting in (11). This allows us to concentrate on Y and, to feature the spatial index, we write Y equivalently as $\{Y(\mathbf{s}) : \mathbf{s} \in D^G\}$. A property of geostatistical processes is that D^G has positive area and hence is uncountable.

Traditionally, a geostatistical process has been specified up to second moments. Starting with the most general specification, we have

$$\mu_Y(\mathbf{s}) \equiv E(Y(\mathbf{s})); \quad \mathbf{s} \in D^G \quad (12)$$

$$C_Y(\mathbf{s}, \mathbf{u}) \equiv \text{cov}(Y(\mathbf{s}), Y(\mathbf{u})); \quad \mathbf{s}, \mathbf{u} \in D^G. \quad (13)$$

From (12) and (13), an optimal spatial linear predictor $\hat{Y}(\mathbf{s}_0)$ of $Y(\mathbf{s}_0)$ can be obtained that depends on spatial data

$\mathbf{Z} \equiv (Z(\mathbf{s}_1), \dots, Z(\mathbf{s}_n))'$. This is an n -dimensional vector indexed by the data's n known spatial locations, $D^{G*} \equiv \{\mathbf{s}_1, \dots, \mathbf{s}_n\} \subset D^G$. In practice, estimation of the parameters θ that specify completely (12) and (13) can be problematic due to the lack of replicated data, so Matheron (1963) made stationarity assumptions that together are now known as *intrinsic stationarity*. That is, for all $\mathbf{s}, \mathbf{u} \in D^G$, assume

$$E(Y(\mathbf{s})) = \mu_Y^0 \quad (14)$$

$$\text{var}(Y(\mathbf{s}) - Y(\mathbf{u})) = 2\gamma_Y^0(\mathbf{s} - \mathbf{u}), \quad (15)$$

where (15) is equal to $C_Y(\mathbf{s}, \mathbf{s}) + C_Y(\mathbf{u}, \mathbf{u}) - 2C_Y(\mathbf{s}, \mathbf{u})$. The quantity $2\gamma_Y^0(\cdot)$ is called the *variogram*, and $\gamma_Y^0(\cdot)$ is called the *semivariogram* (or occasionally the *semivariance*).

If the assumption in (15) were replaced by

$$\text{cov}(Y(\mathbf{s}), Y(\mathbf{u})) = C_Y^0(\mathbf{s} - \mathbf{u}), \text{ for all } \mathbf{s}, \mathbf{u} \in D^G, \quad (16)$$

then (16) and (14) together are known as *second-order stationarity*. Matheron chose (15) because he could derive optimal-spatial-linear-prediction (i.e., kriging) equations of $Y(\mathbf{s}_0)$ without having to know or estimate μ_Y^0 . Here, “optimal” is in reference to a spatial linear predictor $\hat{Y}(\mathbf{s}_0)$ that minimizes the mean-squared prediction error (MSPE),

$$E \left[\left(\hat{Y}(\mathbf{s}_0) - Y(\mathbf{s}_0) \right)^2 \right], \text{ for any } \mathbf{s}_0 \in D^G, \quad (17)$$

where $\hat{Y}(\mathbf{s}_0) \equiv \sum_{i=1}^n \lambda_i Z(\mathbf{s}_i)$. The minimization in (17) is with respect to the coefficients $\{\lambda_i : i = 1, \dots, n\}$ subject to the unbiasedness constraint, $E(\hat{Y}(\mathbf{s}_0)) = E(Y(\mathbf{s}_0))$, or equivalently subject to the constraint $\sum_{i=1}^n \lambda_i = 1$ on $\{\lambda_i\}$. With optimally chosen $\{\lambda_i\}$, $\hat{Y}(\mathbf{s}_0)$ is known as the *kriging predictor*. Matheron called this approach to spatial prediction *ordinary kriging*, although it is known in other fields as BLUP (Best Linear Unbiased Prediction); Cressie (1990) gave the history of kriging and showed that it could also be referred to descriptively as *spatial BLUP*.

The constant-mean assumption (14) can be generalized to $E(Y(\mathbf{s})) \equiv \mathbf{x}(\mathbf{s})'\boldsymbol{\beta}$, for $\mathbf{s} \in D^G$, which is a linear regression where the regression coefficients $\boldsymbol{\beta}$ are unknown and the covariate vector $\mathbf{x}(\mathbf{s})$ includes the entry 1. Under this assumption on $E(Y(\mathbf{s}))$, ordinary kriging is generalized to *universal kriging*, also notated as $\hat{Y}(\mathbf{s}_0)$. Figure 1 shows the universal-kriging predictor of Australian temperature in the month of January 2009, mapped over the whole continent D^G , where the spatial locations $D^{G*} = \{\mathbf{s}_1, \dots, \mathbf{s}_n\}$ of weather stations that supplied the data $\mathbf{Z}$ are superimposed. Formulas for $\hat{Y}(\mathbf{s}_0)$ can be found in, for example, Chilès and Delfiner (2012, Section 3.4).

The optimized MSPE (17) is called the *kriging variance*, and its square root is called the *kriging standard error*:

$$\sigma_k(\mathbf{s}_0) \equiv \left\{ E \left(\left(\hat{Y}(\mathbf{s}_0) - Y(\mathbf{s}_0) \right)^2 \right) \right\}^{1/2}, \text{ for any } \mathbf{s}_0 \in D^G. \quad (18)$$

Figure 2 shows a map over D^G of the kriging standard error associated with the kriging predictor mapped in Fig. 1. It can be shown that a smaller $\sigma_k(\mathbf{s}_0)$ corresponds to a higher density of weather stations near $\mathbf{s}_0$. While ordinary and universal kriging produce an optimal linear predictor, there is an even better predictor, the *best optimal predictor (BOP)*, which is

Spatial Statistics, Fig. 1 Map of a kriging predictor of Australian temperature in January 2009, superimposed on spatial locations of data

Spatial Statistics, Fig. 2 Map of the kriging standard error (18) for the kriging predictor shown in Fig. 1

the best of all the best predictors obtained under a variety of constraints (e.g., linearity). From Bayes' Rule (10), the predictor that minimizes the MSPE (16) without any constraints is $Y^*(\mathbf{s}_0) \equiv E(Y(\mathbf{s}_0) | \mathbf{Z})$, which is the mean of the predictive distribution. Notice that the BOP, $Y^*(\mathbf{s}_0)$, is unbiased, namely, $E(Y^*(\mathbf{s}_0)) = E(Y(\mathbf{s}_0))$, without having to constrain it to be so.

Lattice Processes

In this section, we assume that the spatial locations D are given by D^L , a known countable subset of $\mathbb{R}^d$. This usually represents a collection of grid nodes, pixels, or small areas and the spatial locations associated with them; we write the countable set of all such locations as $D^L \equiv \{\mathbf{s}_1, \mathbf{s}_2, \dots\}$. Each $\mathbf{s}_i$ has a set of neighbors, $\mathcal{N}(\mathbf{s}_i) \subset D^L \setminus \mathbf{s}_i$, associated with it, and whose locations are spatially proximate (and note that a location is not considered to be its own neighbor). Spatial-statistical dependence between locations in lattice processes is defined in terms of these neighborhood relations.

Typically, the neighbors are represented by a spatial-dependence matrix $\mathbf{W}$ with entries w_{ij} nonzero if $\mathbf{s}_j \in \mathcal{N}(\mathbf{s}_i)$, and hence the diagonal entries of $\mathbf{W}$ are all zero. The non-diagonal entries of $\mathbf{W}$ might be, for example, inversely proportional to the distance, $\|\mathbf{s}_i - \mathbf{s}_j\|$, or they might involve some other way of moderating dependence based on spatial proximity. For example, they might be assigned the value 1 if a neighborhood relation exists and 0 otherwise. In this case, $\mathbf{W}$ is called an adjacency matrix, and it is symmetric if $\mathbf{s}_j \in \mathcal{N}(\mathbf{s}_i)$ whenever $\mathbf{s}_i \in \mathcal{N}(\mathbf{s}_j)$ and vice versa.

Consider a lattice process in $\mathbb{R}^2$ defined on the finite grid $D^L = \{(x, y) : x, y = 1, \dots, 5\}$. The first-order neighbors of the grid node (x, y) in the interior of the lattice are the four adjacent nodes, $\mathcal{N}(x, y) = \{(x-1, y), (x, y-1), (x+1, y), (x, y+1)\}$, shown as:

$$\begin{array}{ccccc} \circ & \circ & \circ & \circ & \circ \\ \circ & \circ & \bullet & \circ & \circ \\ \circ & \bullet & \times & \bullet & \circ \\ \circ & \circ & \bullet & \circ & \circ \\ \circ & \circ & \circ & \circ & \circ \end{array}$$

where grid node $\mathbf{s}_i$ is represented by $\times$, and its first-order neighbors are represented by $\bullet$. Nodes situated on the boundary of the grid will have less than four neighbors.

The most common type of lattice process is the *Markov random field* (MRF), which has a conditional-probability property in the spatial domain $\mathbb{R}^d$ that is a generalization of the temporal Markov property found in section “Spatiotemporal Processes”. A lattice process $\{Y(\mathbf{s}) : \mathbf{s} \in D^L\}$ is a MRF if, for all $\mathbf{s}_i \in D^L$, its conditional probabilities satisfy

$$[Y(\mathbf{s}_i) | \mathbf{Y}(D^L \setminus \mathbf{s}_i)] = [Y(\mathbf{s}_i) | \mathbf{Y}(\mathcal{N}(\mathbf{s}_i))], \quad (19)$$

where $\mathbf{Y}(A) \equiv \{Y(\mathbf{s}_j) : \mathbf{s}_j \in A\}$. The MRF is defined in terms of these conditional probabilities (19), which represent statistical dependencies between neighboring nodes that are captured differently from those given by the variogram or the covariance function. Specifically,

$$[Y(\mathbf{s}_i) | \mathbf{Y}(D^L \setminus \mathbf{s}_i)] = \frac{\exp\{-f(Y(\mathbf{s}_i), \mathbf{Y}(\mathcal{N}(\mathbf{s}_i)))\}}{C}, \quad (20)$$

where C is a normalizing constant that ensures the right-hand side of (20) integrates (or sums) to 1. Equation (20) is also known as a Gibbs random field in statistical mechanics since, under regularity conditions, the Hammersley-Clifford Theorem relates the joint probability distribution to the Gibbs measure (Besag 1974). The function $f(Y(\mathbf{s}_i), \mathbf{Y}(\mathcal{N}(\mathbf{s}_i)))$ is referred to as the potential energy, since it quantifies the strength of interactions between neighbors. A wide variety of MRF models can be defined by choosing different forms of the potential-energy function (Winkler 2003, Section 3.2). Note that care needs to be taken to ensure that specification of the model through all the conditional probability distributions, $\{[Y(\mathbf{s}_i) | \mathbf{Y}(\mathcal{N}(\mathbf{s}_i))] : \mathbf{s}_i \in D^L\}$, results in a valid joint probability distribution, $\{[Y(\mathbf{s}_i) : \mathbf{s}_i \in D^L]\}$ (Kaiser and Cressie 2000).

Revisiting the previous simple example of a first-order neighborhood structure on a regular lattice in $\mathbb{R}^2$, notice that grid nodes situated diagonally across from each other are conditionally independent. Hence, D^L can be partitioned into two sub-lattices D_1^L and D_2^L , such that the values at the nodes in D_1^L are independent given the values at the nodes in D_2^L and vice versa (Besag 1974; Winkler 2003, Section 8.1):

$$\begin{array}{ccccc} \bullet & \circ & \bullet & \circ & \bullet \\ \circ & \bullet & \circ & \bullet & \circ \\ \bullet & \circ & \bullet & \circ & \bullet \\ \circ & \bullet & \circ & \bullet & \circ \\ \bullet & \circ & \bullet & \circ & \bullet \end{array}$$

This forms a checkerboard pattern where $\{Y(\mathbf{s}) : \mathbf{s} \in D_1^L\}$ at nodes D_1^L represented by $\bullet$ are mutually independent, given the values $\{Y(\mathbf{u}) : \mathbf{u} \in D_2^L\}$ at nodes D_2^L represented by $\circ$.

Besag (1974) introduced the conditional autoregressive (CAR) model, which is a Gaussian MRF that is defined in terms of its conditional means and variances. We refer the reader to LeSage and Pace (2009) for discussion of a different lattice-process model, known as the simultaneous autoregressive (SAR) model, and a comparison of it with the CAR model. We define the CAR model as follows: For $\mathbf{s}_i \in D^L$, $Y(\mathbf{s}_i)$ is conditionally Gaussian defined by its first and second moments,

$$E(Y(\mathbf{s}_i) | \mathbf{Y}(\mathcal{N}(\mathbf{s}_i))) = \sum_{\mathbf{s}_j \in \mathcal{N}(\mathbf{s}_i)} c_{ij} Y(\mathbf{s}_j) \quad (21)$$

$$\text{var}(Y(\mathbf{s}_i) | \mathbf{Y}(\mathcal{N}(\mathbf{s}_i))) = \tau_i^2, \quad (22)$$

where c_{ij} are spatial autoregressive coefficients such that the diagonal elements $c_{1,1} = \dots = c_{n,n} = 0$, and $\{\tau_i^2\}$ are the variability parameters for the locations $\{\mathbf{s}_i\}$, respectively. Under an important regularity condition (see below), this specification results in a joint probability distribution that is multivariate Gaussian. That is,

$$\mathbf{Y} \sim \text{Gau}(\mathbf{0}, (\mathbf{I} - \mathbf{C})^{-1} \mathbf{M}), \quad (23)$$

where $\text{Gau}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ denotes a Gaussian distribution with mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$; the matrix $\mathbf{M} \equiv \text{diag}(\tau_1^2, \dots, \tau_n^2)$ is diagonal; and the regularity condition referred to above is that the coefficients $\mathbf{C} \equiv \{c_{ij}\}$ in (21) have to result in $\mathbf{M}^{-1}(\mathbf{I} - \mathbf{C})$ being a symmetric and positive-definite matrix. With a first-order neighborhood structure, such as shown in the simple example above in $\mathbb{R}^2$, the precision matrix is block-diagonal, which makes it possible to sample efficiently from this Gaussian MRF using sparse-matrix methods (Rue and Held 2005, Section 2.4).

The data vector for lattice processes is $\mathbf{Z} \equiv (Z(\mathbf{s}_1), \dots, Z(\mathbf{s}_n))'$, where $D^{L*} \equiv \{\mathbf{s}_1, \dots, \mathbf{s}_n\} \subset D^L$. As for the previous subsection, the data model is $[\mathbf{Z} | \{Y(\mathbf{s}) : \mathbf{s} \in D^L\}]$ which, to emphasize dependence on parameters θ , we reactivate earlier notation and write as $[\mathbf{Z} | Y, \theta]$. Now, if we write the lattice-process model as $[\{Y(\mathbf{s}) : \mathbf{s} \in D^L\} | \theta] \equiv [Y | \theta]$, then estimation of θ follows by maximizing the likelihood, $\mathcal{L}(\theta) \equiv \int [\mathbf{Z} | Y, \theta] [Y | \theta] dY$.

Regarding spatial prediction, $Y^*(\mathbf{s}_0) \equiv E(Y(\mathbf{s}_0) | \mathbf{Z}, \theta)$ is the best optimal predictor of $Y(\mathbf{s}_0)$, for $\mathbf{s}_0 \in D^L$ and known θ (e.g., Besag et al. 1991). Note that $\mathbf{s}_0$ may not belong to D^{L*} , and hence $Y^*(\mathbf{s}_0)$ is a predictor of $Y(\mathbf{s}_0)$ even when there is no datum observed at the node $\mathbf{s}_0$. Inference on unobserved parts of the process Y is just as important for lattice processes as it is for geostatistical processes.

Spatial Point Processes and Random Sets

A spatial point process is a countable collection of *random locations* $D \equiv D^P \subset \mathcal{D}$. Closely related to this random set of points is the counting process that we shall call $\{N(A) : A \subset \mathcal{D}\}$, where recall that $\mathcal{D}$ indexes all possible locations of interest, and now we assume it is bounded. For example, if A is a given subset of $\mathcal{D}$, and two of the random points $\{\mathbf{s}_i\}$ are contained in A , then $N(A) = 2$. Since $D^P = \{\mathbf{s}_i\}$ is

random and A is fixed, $N(A)$ is a random variable defined on the non-negative integers.

Clearly, the joint distributions $[N(A_1), \dots, N(A_m)]$, for any subsets $\{A_j : j = 1, \dots, m\}$ contained in $\mathcal{D}$ (possibly overlapping) and for any $m = 0, 1, 2, \dots$, are well defined. Spatial dependence can be seen through the spatial proximity between the $\{A_j\}$. Consider just two fixed subsets, A_1 and A_2 (i.e., $m = 2$) and, to avoid ambiguity caused by potentially sharing points, let $A_1 \cap A_2$ be empty. Then no spatial dependence is exhibited if, for any disjoint A_1 and A_2 , there is statistical independence; that is,

$$[N(A_1), N(A_2)] = [N(A_1)][N(A_2)]. \quad (24)$$

The basic spatial point process known as the *Poisson point process* has the independence property (24), and its associated counting process satisfies

$$[N(A)] = \exp\{-\lambda(A)\} \frac{\lambda(A)^{N(A)}}{N(A)!}; \quad A \subset \mathcal{D}, \quad (25)$$

where $\lambda(A) \equiv \int_A \lambda(\mathbf{s}) d\mathbf{s}$. In (25), $\lambda(\cdot)$ is a given intensity function defined according to:

$$\lambda(\mathbf{s}) \equiv \lim_{|\delta\mathbf{s}| \rightarrow 0} \frac{E(Y(\delta\mathbf{s}))}{|\delta\mathbf{s}|}, \quad (26)$$

where $\delta\mathbf{s}$ is a small set centered at $\mathbf{s} \in \mathcal{D}$, and whose volume $|\delta\mathbf{s}|$ tends to 0.

In (25), the special case of $\lambda(\mathbf{s}) \equiv \lambda$, for all $\mathbf{s} \in \mathcal{D}$, results in a *homogeneous Poisson point process*, and a simulation of it is shown in Fig. 3. The simulation was obtained using an equivalent probabilistic representation for which the count random variable $N(\mathcal{D})$, for $\mathcal{D} = [0, 1] \times [0, 1]$, was simulated

Spatial Statistics, Fig. 3 A realization on the unit square $\mathcal{D} = [0, 1] \times [0, 1]$, of the homogeneous Poisson point process (25) with parameter $\lambda = 50$; for this realization, $N(\mathcal{D}) = 46$

according to (25). Then, conditional on $N(\mathcal{D})$, $\{\mathbf{s}_1, \dots, \mathbf{s}_{N(\mathcal{D})}\}$ was simulated independently and identically according to the uniform distribution,

$$[\mathbf{u}] = \begin{cases} \frac{1}{\lambda(\mathcal{D})}; & \mathbf{u} \in \mathcal{D} \\ 0; & \text{elsewhere.} \end{cases} \quad (27)$$

This representation explains why the homogenous Poisson point process is commonly referred to as a *Completely Spatially Random* (CSR) process, and why it is used as a baseline for testing for the absence of spatial dependence in a point process. That is, before a spatial model is fitted to a point pattern, a test of the null hypothesis that the point pattern originates from a CSR process, is often carried out. Rejection of CSR then justifies the fitting of spatially dependent point processes to the data (e.g., Ripley 1981; Diggle 2013).

Much of the early research in point processes was devoted to establishing test statistics that were sensitive to various types of departures from the CSR process (e.g., Cressie 1993, Section 8.2). This was followed by researchers' defining and then estimating spatial-dependence measures such as the second-order-intensity function and the K-function (e.g., Ripley 1981, Chapter 8), where inference was often in terms of method-of-moments estimation of these functions. More efficient likelihood-based inference came later; Baddeley et al. (2015) give a comprehensive review of these methodologies for point processes. From a modeling perspective, particular attention has been paid to the log-Gaussian Cox point processes; here, $\lambda(\cdot)$ in (25) is random, such that $\{\log(\lambda(\mathbf{s})) : \mathbf{s} \in \mathcal{D}\}$ is a Gaussian process (e.g., Møller and Waagepetersen 2003). This model leads naturally to hierarchical Bayesian inference for $\lambda(\cdot)$ and its parameters (e.g., Gelfand and Schliep 2018).

If an attribute process, $\{Y(\mathbf{s}_i) : \mathbf{s}_i \in D^P\}$, is included with the spatial point process D^P , one obtains a so-called *marked point process* (e.g., Cressie 1993, Section 8.7). For example, the study of a natural forest where both the locations $\{\mathbf{s}_i\}$ and the sizes of the trees $\{Y(\mathbf{s}_i)\}$ are modeled together probabilistically, results in a marked point process where the "mark" process is a spatial process $\{Y(\mathbf{s}_i) : \mathbf{s}_i \in D^P\}$ of tree size. Now, Bayes' Rule given by (10), where both Y and $D (= D^P)$ are random, should be used to make inference on Y and D^P through the predictive distribution $[Y, D^P | \mathbf{Z}]$. Here, $\mathbf{Z}$ consists of the number of trees, the trees' locations, and the trees' size measurements, as denoted in (5). After marginalization, we can obtain $[D^P | \mathbf{Z}]$, the predictive distribution of the spatial point process D^P .

A spatial point process is a special case of a random set, which is a random quantity in Euclidean space that was defined rigorously by Matheron (1975). Some geological

processes are more naturally modeled as set-valued phenomena (e.g., the facies of a mineralization); however, inference for random-set processes has lagged behind those for spatial point processes. It is difficult to define a likelihood based on set-valued data, which has held back statistically efficient inferences; nevertheless, basic method-of-moment estimators are often available. The most well-known random set that allows statistical inference from set-valued data is the Boolean Model (e.g., Cressie and Wikle 2011, Section 4.4).

Multivariate Spatial Processes

The previous subsections have presented single spatial statistical processes but, as models become more realistic representations of a complex world, there is a need to express interactions between multiple processes. This is most directly seen by modeling vector-valued geostatistical processes $\{\mathbf{Y}(\mathbf{s}) : \mathbf{s} \in D^G\}$, and vector-valued lattice processes $\{\mathbf{Y}(\mathbf{s}_i) : \mathbf{s}_i \in D^L\}$, where the k -dimensional vector $\mathbf{Y}(\mathbf{s}) \equiv (Y_1(\mathbf{s}), \dots, Y_k(\mathbf{s}))'$ represents the multiple processes at the generic location $\mathbf{s} \in \mathcal{D}$. Vector-valued spatial point processes can be represented as a set of k point processes, $\{\{\mathbf{s}_{1,i}\}, \dots, \{\mathbf{s}_{k,i}\}\}$, and these are presented in Baddeley et al. (2015, Chapter 14). If we adopt a hierarchical-statistical-modeling approach, it is possible to construct multivariate spatial processes whose component univariate processes could come from any of the three types of spatial processes presented in the previous three subsections. This is because, at a deeper level of the hierarchy, a core *multivariate geostatistical process* can control the spatial dependence for processes of any type, which allows the possibility of hybrid multivariate spatial statistical processes.

In what follows, we describe briefly two approaches to constructing multivariate geostatistical processes, one based on a joint approach and the other based on a conditional approach. We consider the case $k = 2$, namely, the bivariate spatial process $\{(Y_1(\mathbf{s}), Y_2(\mathbf{s}))' : \mathbf{s} \in D^G\}$, for illustration. The joint approach involves directly constructing a valid spatial statistical model from $\boldsymbol{\mu}(\mathbf{s}) \equiv (\mu_1(\mathbf{s}), \mu_2(\mathbf{s}))' \equiv (E(Y_1(\mathbf{s})), E(Y_2(\mathbf{s})))'$, for $\mathbf{s} \in D^G$, and from

$$\text{cov}(Y_l(\mathbf{s}), Y_m(\mathbf{u})) \equiv C_{lm}(\mathbf{s}, \mathbf{u}); l, m = 1, 2, \quad (28)$$

for $\mathbf{s}, \mathbf{u} \in D^G$. The bivariate-process mean $\boldsymbol{\mu}(\cdot)$ is typically modeled as a vector linear regression; hence it is straightforward to model the bivariate mean once the appropriate regressors have been chosen.

Analogous to the univariate case, the set of covariance and cross-covariance functions, $\{C_{11}(\cdot, \cdot), C_{22}(\cdot, \cdot), C_{12}(\cdot, \cdot), C_{21}(\cdot, \cdot)\}$, have to satisfy positive-definiteness conditions for the bivariate geostatistical model to be valid, and it is important to note that, in general, $C_{12}(\mathbf{s}, \mathbf{u}) \neq C_{21}(\mathbf{s}, \mathbf{u})$. There are classes of valid models that exhibit symmetric cross-

dependence, namely, $C_{12}(\mathbf{s}, \mathbf{u}) = C_{21}(\mathbf{s}, \mathbf{u})$, such as the linear model of co-regionalization (Gelfand et al. 2004). These are not reasonable models for ore-reserve estimation when there has been preferential mineralization in the ore body.

The joint approach can be contrasted with a conditional approach (Cressie and Zammit-Mangion 2016), where each of the k processes is a node of a directed acyclic graph that guides the conditional dependence of any process, given the remaining processes. Again consider the bivariate case (i.e., $k = 2$), where there are only two nodes such that $Y_1(\cdot)$ is at node 1, $Y_2(\cdot)$ is at node 2, and a directed edge is declared from node 1 to node 2. Then the appropriate way to model the joint distribution is through

$$[Y_1(\cdot), Y_2(\cdot)] = [Y_2(\cdot) | Y_1(\cdot)] [Y_1(\cdot)], \quad (29)$$

where $[Y_2(\cdot) | Y_1(\cdot)]$ is shorthand for $[Y_2(\cdot) | \{Y_1(\mathbf{s}) : \mathbf{s} \in D^G\}]$.

The geostatistical model for $[Y_1(\cdot)]$ is simply a univariate spatial model based on a mean function $\mu_1(\cdot)$ and a valid covariance function $C_{11}(\cdot, \cdot)$, which was discussed in section “Geostatistical Processes”. Now assume that $Y_2(\cdot)$ depends on $Y_1(\cdot)$ as follows: For $\mathbf{s}, \mathbf{u} \in D^G$,

$$\begin{aligned} E[Y_2(\mathbf{s}) | Y_1(\cdot)] &\equiv \mu_2(\mathbf{s}) + \int_{D^G} b(\mathbf{s}, \mathbf{v}) \\ &\quad \times (Y_1(\mathbf{v}) - \mu_1(\mathbf{v})) \, d\mathbf{v}, \end{aligned} \quad (30)$$

$$\text{cov}(Y_2(\mathbf{s}), Y_2(\mathbf{u}) | Y_1(\cdot)) \equiv C_{2|1}(\mathbf{s}, \mathbf{u}), \quad (31)$$

where $C_{2|1}(\cdot, \cdot)$ is a valid univariate covariance function and $b(\cdot, \cdot)$ is an integrable interaction function. The conditional-moment assumptions given by (30) and (31) follow if one assumes that $(Y_1(\cdot), Y_2(\cdot))'$ is a bivariate Gaussian process.

Cressie and Zammit-Mangion (2016) show that, from (30) and (31),

$$C_{12}(\mathbf{s}, \mathbf{u}) = \int_{D^G} C_{11}(\mathbf{s}, \mathbf{v}) b(\mathbf{u}, \mathbf{v}) \, d\mathbf{v} \quad (32)$$

$$C_{21}(\mathbf{s}, \mathbf{u}) = \int_{D^G} C_{11}(\mathbf{v}, \mathbf{u}) b(\mathbf{v}, \mathbf{s}) \, d\mathbf{v} \quad (33)$$

$$\begin{aligned} C_{22}(\mathbf{s}, \mathbf{u}) &= C_{2|1}(\mathbf{s}, \mathbf{u}) \\ &\quad + \int_{D^G} \int_{D^G} b(\mathbf{s}, \mathbf{v}) C_{11}(\mathbf{v}, \mathbf{w}) b(\mathbf{u}, \mathbf{w}) \, d\mathbf{v} \, d\mathbf{w}, \end{aligned} \quad (34)$$

for $\mathbf{s}, \mathbf{u} \in D^G$. Along with $\mu_1(\cdot)$, $\mu_2(\cdot)$, and $C_{11}(\cdot, \cdot)$, these functions (32)–(34) define a valid bivariate geostatistical process $[Y_1(\cdot), Y_2(\cdot)]$. A notable property of the conditional approach is that asymmetric cross-dependence (i.e., $C_{12}(\mathbf{s}, \mathbf{u}) \neq C_{21}(\mathbf{s}, \mathbf{u})$) occurs if $b(\mathbf{s}, \mathbf{u}) \neq b(\mathbf{u}, \mathbf{s})$.

In summary, the conditional approach allows multivariate modeling to be carried out validly by simply specifying $\boldsymbol{\mu}(\cdot) = (\mu_1(\cdot), \mu_2(\cdot))'$ and two valid univariate covariance functions, $C_1(\cdot, \cdot)$ and $C_{2|1}(\cdot, \cdot)$. The strengths of the conditional approach are that only univariate covariance functions need to be specified (for which there is a very large body of research; e.g., Cressie and Wikle 2011, Chapter 4), and that only integrability of $b(\cdot, \cdot)$, the interaction function, needs to be assumed (Cressie and Zammit-Mangion 2016).

Spatial Discretization

Although geostatistical processes are defined on a continuous spatial domain D^G , this can limit the practical feasibility of statistical inferences due to computational and mathematical considerations. For example, kriging from an n -dimensional vector of data involves the inversion of an $n \times n$ covariance matrix, which requires order n^3 floating-point operations and order n^2 storage in available memory. These costs can be prohibitive for large spatial datasets; hence, spatial discretization to achieve scalable computation for spatial models is an active area of research.

In practical applications, spatial statistical inference is required up to a finite spatial resolution. Many approaches take advantage of this by dividing the spatial domain $\mathcal{D}$ into a lattice of discrete points in $\mathcal{D}$, as shown in Fig. 4. As a consequence of this discretization, a geostatistical process can be approximated by a lattice process, such as a Gaussian MRF (e.g., Rue and Held 2005, Section 5.1); however, sometimes this can result in undesirable discretization errors and artifacts. More sophisticated approaches have been developed

Spatial Statistics, Fig. 4 Discretization of the spatial domain $\mathcal{D}$, a convex region around Australia, into a triangular lattice

to obtain highly accurate approximations of a geostatistical (i.e., continuously indexed) spatial process evaluated over an irregular lattice, as we now discuss.

Let the original domain $\mathcal{D}$ be bounded and suppose it is tessellated into the areas $\{A_j \subset \mathcal{D} : j = 1, \dots, m\}$ that are small, non-overlapping *basic areal units* (BAUs; Nguyen et al. 2012), so that $\mathcal{D} = \bigcup_{j=1}^m A_j$, and $A_j \cap A_k$ is the empty set for any $j \neq k \in \{1, \dots, m\}$; Fig. 4 gives an example of triangular BAUs. Spatial basis functions $\{\phi_\ell(\cdot) : \ell = 1, \dots, r\}$, can then be defined on the BAUs. For example, Lindgren et al. (2011) used triangular basis functions where $r > m$, while fixed rank kriging (FRK; Cressie and Johannesson 2008; Zammit-Mangion and Cressie 2021) can employ a variety of different basis functions for $r < m$, including multi-resolution wavelets and bisquares.

Vecchia approximations (e.g., Datta et al. 2016; Katzfuss et al. 2020) are also defined using a lattice of discrete points $D^L \subset D^G \subset \mathcal{D}$, that include the coordinates of the observed data $D^{G*} = \{\mathbf{s}_1, \dots, \mathbf{s}_n\}$ and the prediction locations $\{\mathbf{s}_{n+1}, \dots, \mathbf{s}_{n+p}\}$. Let $[\mathbf{X}] \equiv [\mathbf{Z}, \mathbf{Y}]$, where data $\mathbf{Z}$ and spatial process $\mathbf{Y}$ are associated with the lattice $D^L \equiv \{\mathbf{s}_1, \dots, \mathbf{s}_n, \mathbf{s}_{n+1}, \dots, \mathbf{s}_{n+p}\}$. It is a property of joint and conditional distributions that this can be factorized into a product:

$$[\mathbf{X}] = [X(\mathbf{s}_1)] \prod_{i=2}^{n+p} [X(\mathbf{s}_i) | X(\mathbf{s}_1), \dots, X(\mathbf{s}_{i-1})]. \quad (35)$$

In the previous section, the set of spatial coordinates D^L had no fixed ordering. However, a Vecchia approximation requires that an artificial ordering is imposed on $\{\mathbf{s}_1, \dots, \mathbf{s}_{n+p}\}$. Let the ordering be denoted by $\{\mathbf{s}_{(1)}, \dots, \mathbf{s}_{(n+p)}\}$, and define the set of neighbors $\mathcal{N}(\mathbf{s}_{(i)}) \subset \{\mathbf{s}_{(1)}, \dots, \mathbf{s}_{(i-1)}\}$, similarly to “Lattice Processes,” except that these neighborhood relations are not reciprocal: If for $j < i$, $\mathbf{s}_{(j)}$ belongs to $\mathcal{N}(\mathbf{s}_{(i)})$, then $\mathbf{s}_{(i)}$ cannot belong to $\mathcal{N}(\mathbf{s}_{(j)})$. As part of the Vecchia approximation, a fixed upper bound $q \ll n$ on the number of neighbors is chosen. That is, $|\mathcal{N}(\mathbf{s}_{(i)})| \leq q$, so that the lattice formed by $\{\mathcal{N}(\mathbf{s}_{(i)}) : i = 1, \dots, n+p\}$ is a directed acyclic graph, which results in a partial order in $\mathcal{D}$.

The joint distribution $[\mathbf{X}]$ given by (35) is then approximated by:

$$[X(\mathbf{s}_{(1)})] \prod_{i=2}^{n+p} [X(\mathbf{s}_{(i)}) | \mathbf{X}(\mathcal{N}(\mathbf{s}_{(i)}))] \equiv [\tilde{\mathbf{X}}], \quad (36)$$

which is a Partially Ordered Markov Model (POMM; Cressie and Davidson 1998). This Vecchia approximation, $[\tilde{\mathbf{X}}]$, is a distribution coming from a valid spatial process on the original, uncountable, unordered index set D^G (Datta et al. 2016), which means that it can be used as a geostatistical process model with considerable computational advantages. For

example, it can be used as a random log-intensity function, $\log(\lambda(\mathbf{s}))$, in a hierarchical point-process model, or it can be combined with other processes to define models described in section “Multivariate Spatial Processes”. However, in all of these contexts it should be remembered that the resulting predictive process, $[\tilde{\mathbf{X}} | \mathbf{Z}]$, is an approximation to the true predictive process, $[\mathbf{X} | \mathbf{Z}]$.

Spatiotemporal Processes

The section “Multivariate Spatial Processes” introduced processes that were written in vector form as,

$$\mathbf{Y}(\mathbf{s}) \equiv (Y_1(\mathbf{s}), \dots, Y_k(\mathbf{s}))'; \mathbf{s} \in D^G. \quad (37)$$

In that section, we distinguished between the joint approach and the conditional approach to multivariate-spatial-statistical modeling and, under the conditional approach, we used a directed acyclic graph to give a blueprint for modeling the multivariate spatial dependence.

Now, consider a spatiotemporal process,

$$\{Y(\mathbf{s}; t) : \mathbf{s} \in D^G; t \in \mathcal{T}\}, \quad (38)$$

where $\mathcal{T}$ is a temporal index set. Clearly, if $\mathcal{T} = \{1, 2, \dots\}$ then (38) becomes a spatial process of time series, $\{Y(\mathbf{s}; 1), Y(\mathbf{s}; 2), \dots : \mathbf{s} \in D^G\}$. If $\mathcal{T} = \{1, 2, \dots, k\}$, and we define $Y_j(\mathbf{s}) \equiv Y(\mathbf{s}; j)$, for $j = 1, \dots, k$, then the resulting spatiotemporal process can be represented as a multivariate spatial process given by (37). Not surprisingly, the same dichotomy of approach to modeling statistical dependence (i.e., joint versus conditional) occurs for spatiotemporal processes as it does for multivariate spatial processes.

Describing all possible covariances between Y at any spatiotemporal “location” $(\mathbf{s}; t)$ and any other one $(\mathbf{u}; v)$, amounts to treating “time” as simply another dimension to be added to the d -dimensional Euclidean space, $\mathbb{R}^d$. Taking this approach, spatiotemporal statistical dependence can be expressed in $(d+1)$ -dimensional space through the covariance function,

$$C(\mathbf{s}; t, \mathbf{u}; v) \equiv \text{cov}(Y(\mathbf{s}; t), Y(\mathbf{u}; v)); \quad \mathbf{s}, \mathbf{u} \in D^G, t, v \in \mathcal{T}. \quad (39)$$

Of course, the time dimension has different units than the spatial dimensions, and its interpretation is different since the future is unobserved. Hence, the joint modeling of space and time based on (39) must be done with care to account for the special nature of the time dimension in this *descriptive approach* to spatiotemporal modeling.

From current and past spatiotemporal data $\mathbf{Z}$, predicting past values of Y is called *smoothing*, predicting unobserved values of the current Y is called *filtering*, and predicting future values of Y is called *forecasting*. The Kalman filter (Kalman 1960) was developed to provide fast predictions of the current state using a methodology that recognizes the ordering of the time dimension. Today's filtered values become "old" the next day when a new set of current data are received. Using a dynamical approach that we shall now describe, the Kalman filter updates yesterday's optimal filtered value with today's data very rapidly, to obtain a current optimal filtered value.

The best way to describe the dynamical approach is to discretize the spatial domain. The previous section "[Spatial Discretization](#)", describes a number of ways this can be done; here we shall consider the discretization that is most natural for storing the attribute and location information in computer memory, namely, a fine-resolution lattice D^L of pixels or voxels (short for "volume elements"). Replace $\{Y(\mathbf{s};t) : \mathbf{s} \in D^G, t = 1, 2, \dots\}$ with $\{Y(\mathbf{s};t) : \mathbf{s} \in D^L, t = 1, 2, \dots\}$, where $D^L \equiv \{\mathbf{s}_1, \dots, \mathbf{s}_m\}$ are the centroids of elements of small area (or small volume) that make up D^G . Often the areas of these elements are equal, having been defined by a regular grid. As we explain below, this allows a *dynamical approach* to constructing a statistical model for the spatiotemporal process Y on the discretized space-time cube, $\{\mathbf{s}_1, \dots, \mathbf{s}_m\} \times \{1, 2, \dots\}$.

Define $\mathbf{Y}_t \equiv (Y(\mathbf{s};t) : \mathbf{s} \in D^L)'$, which is an m -dimensional vector. Because of the temporal ordering, we can write the joint distribution of $\{Y(\mathbf{s};t) : \mathbf{s} \in D^L, t = 1, \dots, k\}$ from $t = 1$ up to the present time $t = k$, as

$$[\mathbf{Y}_1, \mathbf{Y}_2, \dots, \mathbf{Y}_k] = [\mathbf{Y}_1] \times [\mathbf{Y}_2 | \mathbf{Y}_1] \dots [\mathbf{Y}_k | \mathbf{Y}_{k-1}, \dots, \mathbf{Y}_2, \mathbf{Y}_1], \quad (40)$$

which has the same form as (35). Note that this conditional modeling of space and time is a natural approach, since time is completely ordered. The next step is to make a Markov assumption, and hence (40) can be written as

$$[\mathbf{Y}_1, \mathbf{Y}_2, \dots, \mathbf{Y}_k] = [\mathbf{Y}_1] \prod_{j=2}^k [\mathbf{Y}_j | \mathbf{Y}_{j-1}]. \quad (41)$$

This is the same Markov property that we previously discussed in section "[Lattice Processes](#)", except it is now applied to the completely ordered one-dimensional domain, $\mathcal{T} = \{1, 2, \dots\}$, and $\mathcal{N}(j) = j - 1$. The Markov assumption makes our approach dynamical: It says that the present, conditional on the past, in fact only depends on the "most recent past." That is, since $\mathcal{N}(j) = j - 1$, the factor $[\mathbf{Y}_j | \mathbf{Y}_{j-1}, \dots, \mathbf{Y}_2, \mathbf{Y}_1] = [\mathbf{Y}_j | \mathbf{Y}_{j-1}]$, which results in the model (41).

For further information on the types of models used in the descriptive approach given by (39) and the types of models used in the dynamical approach given by (41), see Cressie and

Wikle (2011, Chapters 6–8) and Wikle et al. (2019, Chapters 4 and 5). The statistical analysis of observations from these processes is known as *spatiotemporal statistics*. Inference (estimation and prediction) from spatiotemporal data using R software can be found in Wikle et al. (2019).

Conclusion

Spatial-statistical methods distinguish themselves from spatial-analysis methods found in the geographical and environmental sciences, by providing well-calibrated quantification of the uncertainty involved with estimation or prediction. Uncertainty in the scientific phenomenon of interest is represented by a spatial *process model*, $\{Y(\mathbf{s}) : \mathbf{s} \in D\}$, defined on possibly random D in $\mathbb{R}^d$, while measurement uncertainty in the observations $\mathbf{Z}$ is represented in a *data model*. In section "[Introduction](#)", we saw how these two models are combined using Bayes' Rule (10), or the simpler version (11), to calculate the overall uncertainty needed for statistical inference.

There are three main types of spatial process models: geostatistical processes where uncertainty is in the process Y , which is indexed continuously in $D = D^G$; lattice processes where uncertainty is also in Y , but now Y is indexed over a countable number of spatial locations $D = D^L$; and point processes where uncertainty is in the spatial locations $D = D^P$. Multiple spatial processes can interact with each other to form a multivariate spatial process. Importantly, processes can vary over time as well as spatially, forming a spatiotemporal process.

With some exceptions, spatial-statistical models (1) rarely consider the case of measurement error in the locations in $\mathcal{D}$. Here we focus on a spatial-statistical model for the location error (Cressie and Kornak 2003): Write the observed locations as $D^* \equiv \{\mathbf{u}_i : i = 1, \dots, n\}$; in this case, a part of the data model is $[D^* | D]$, and a part of the process model is $[D]$. Finally then, the data consist of both locations and attributes and are $\mathbf{Z} \equiv \{(\mathbf{u}_i, Z(\mathbf{u}_i)) : i = 1, \dots, n\}$, the spatial process model is $[Y, D]$, and the data model is $[\mathbf{Z} | Y, D]$. Then Bayes' Rule given by (10) is used to infer the unknowns Y and D from the predictive distribution $[Y, D | \mathbf{Z}]$.

As the size of spatial datasets have been increasing dramatically, more and more attention has been devoted to scalable computation for spatial-statistical models. Of particular interest are methods that use spatial discretization to approximate a continuous spatial domain, D^G . There are other recent advances in spatial statistics that we feel are important to mention, but their discussion here is necessarily brief.

Physical barriers can sometimes interrupt the statistical association between locations in close spatial proximity. Barrier models (Bakka et al. 2019) have been developed to account for these kinds of discontinuities in the spatial correlation function. Other methods for modeling nonstationarity,

anisotropy, and heteroskedasticity in spatial process models are an active area of research.

It can often be difficult to select appropriate prior distributions for the parameters of a stationary spatial process, for example its correlation-length scale. Penalized complexity (PC) priors (Simpson et al. 2017) are a way to encourage parsimony by favoring parameter values that result in the simplest model consistent with the data. The likelihood function of a point process or of a non-Gaussian lattice model can be both analytically and computationally intractable. Surrogate models, emulators, and quasi-likelihoods have been developed to approximate these intractable likelihoods (Moore et al. 2020).

Copulas are an alternative method for modeling spatial dependence in multivariate data, particularly when the data are non-Gaussian (Krupskii and Genton 2019). One area where non-Gaussianity can arise is in modeling the spatial association between extreme events, such as for temperature or precipitation (Tawn et al. 2018; Bacro et al. 2020).

As a final comment, we reflect on how the field of geostatistics has evolved, beginning with applications of spatial stochastic processes to mining: In the 1970s, Georges Matheron and his Centre of Mathematical Morphology in Fontainebleau were part of the Paris School of Mines, a celebrated French tertiary-education and research institution. To see what the geostatistical methodology of the time was like, the interested reader could consult Journel and Huijbregts (1978), for example. Over the following decade, geostatistics became notationally and methodologically integrated into statistical science and the growing field of spatial statistics (e.g., Ripley 1981; Cressie 1993). It took one or two more decades before geostatistics became integrated into the hierarchical-statistical-modeling approach to spatial statistics (e.g., Banerjee et al. 2003; Cressie and Wikle 2011, Chapter 4). The presentation given in our review takes this latter viewpoint and explains well-known geostatistical quantities such as the variogram and kriging in terms of this advanced, modern view of geostatistics. We also include a discussion of uncertainty in the spatial index set as part of our review, which offers new insights into spatial-statistical modeling. Probabilistic difficulties with geostatistics, of making inference on a possibly non-countable number of spatial random variables from a finite number of observations, can be finessed by discretizing the process. In a modern computing environment, this is key to carrying out spatial-statistical inference (including kriging).

Definition

The term spatio-temporal is associated with a wide area of research, which aims to provide methods and tools for analyzing the evolution of a phenomenon over a spatial and temporal domain. There are many variables that can be viewed as phenomena with a spatio-temporal variability, such as meteorological readings (temperature, humidity, pressure), hydrological parameters (permeability and hydraulic conductivity), and many measures of air, soil, and water pollution. In this context, methods for analyzing and explaining the joint spatio-temporal behavior of the above variables are necessary in order to get different goals: optimization of sampling design network, estimation at unsampled spatial locations or unsampled times and computation of maps of predicted values, assessing the uncertainty of predicted values starting from the experimental measurements, trends' detection in space and time, particularly important to cope with risks coming from concentrations of hazardous pollutants. Hence, more and more attention is given to the spatial-temporal analysis in order to sort out these issues. The term spatio-temporal and space-time are generally used interchangeably in literature.

Geostatistical Approach

Geostatistics is a branch of spatial and spatio-temporal statistics that uses the formalism of random functions to analyze data characterized by spatial or spatio-temporal structure. It is assumed that the data relate to a phenomenon with an underlying continuous evolution, and thus other types of phenomena, e.g., lattice or point processes, are excluded from geostatistical analysis and are not the object of this contribution. Geostatistics was born to solve mining engineering problems; however, the domain of geostatistical applications

is much broader to date. Important contributions to the current knowledge about space-time models can be also found in Kyriakidis and Journel (1999) as well as in Christakos (2017), which skillfully combine theory and modeling aspects. A recent text by Cressie and Wikle (2011) presents a statistical approach to spatio-temporal data modeling from the perspective of Bayesian Hierarchical Modeling.

The main advantages of geostatistical techniques in modeling spatio-temporal variables are related to the possibility of:

- Choosing an appropriate spatio-temporal model for the non-constant mean (or deterministic component), if any. Note that there are no restrictions in the methods or in the models to be used to define the deterministic component.
- Analyzing both the spatial distribution and the temporal evolution of the data (or the trend residuals) through a spatio-temporal correlation measure (variogram or covariance function).

This paper provides an introduction to the spatio-temporal random function (*STRF*) theory, together with modeling tools and prediction methods based on kriging. Note that the terms random function and random field are equivalent, although this last terminology is less common.

Space-Time Domain

The natural domain for a geostatistical space-time model is $\mathbb{R}^d \times \mathbb{R}$, where $\mathbb{R}^d$ stands for the d -dimensional spatial domain ($d \in \mathbb{N}_+$) and $\mathbb{R}$ for the temporal domain. From a purely mathematical perspective, $\mathbb{R}^d \times \mathbb{R} = \mathbb{R}^{d+1}$, thus there are no differences between the coordinates. However, physically there is a clear-cut separation between the spatial and time dimensions, and a realistic statistical model will take account of it. It is worth to underline that all technical results on spatial covariance functions or on least-squares prediction, or kriging, in Euclidean spaces apply directly to space-time problems, simply by separating the vector $\mathbf{u}$ (representing a point in space-time), into its spatial and temporal components, that is, $\mathbf{s}$ and t , respectively.

Other spatio-temporal domains are also relevant in practice even if they are not used hereafter. Monitoring data are frequently observed at fixed temporal lags, and it might be useful to model a random function on $\mathbb{R}^d \times \mathbb{Z}$, with time considered discrete. In atmospheric and geophysical applications, the spatial domain of interest is frequently expansive or global and the curvature of the Earth has to be considered; thus, the spatio-temporal domain is defined as $\mathbb{S} \times \mathbb{R}$ or $\mathbb{S} \times \mathbb{Z}$, where $\mathbb{S}$ denotes a sphere in the three-dimensional space.

Problems in Space-Time

Although spatio-temporal estimation techniques can be viewed as an extension of the spatial ones or, alternatively, of the temporal ones, a number of theoretical and practical problems must be addressed. These problems are related to the following aspects:

- Differences between spatial and temporal phenomena
- Data characteristics
- Metric in space-time

Among the fundamental differences between spatial and temporal phenomena, it is worth mentioning that, while there is the notion of past, present, and future in time, conversely, in a spatial context, there is in general no ordering; in particular, only directional dependence, known as anisotropy, may be found.

A typical characteristic of the space-time data is related to the data sampling. Usually, a restricted number of survey stations are established in space, while an intense sampling in time is available at each spatial point. A poor monitoring network is often due to the relatively high cost of the sampling devices and the accessibility of sampling sites. On the other hand, long times series can be easily obtained at each spatial location. Thus, the most common data sets in a space-time context are sparse in space and dense in time. As a consequence, the spatial and temporal correlations are estimated with different degrees of reliability and accuracy.

Moreover, temporal periodicity is often associated with non-stationarity in space, and, in many cases, while the temporal periodicity is limited to the first moment, the non-stationarity in space is extended to higher order moments. With respect to time, periodic functions are often combined (with deterministic or stochastic coefficients) in order to describe seasonal components with a certain period (i.e. daily, weekly, monthly cycles according to the features of the examined variable and temporal aggregation) and different amplitudes and phases. In the presence of quasi-periodic temporal behavior with varying periods, amplitudes, and phases, it is common to assume linear or quadratic trends, unless long time series allow to detect and model a more complex functional form for the mean component. As regards the spatial non-stationarity, a wide class of drift functions is represented by polynomials or, in general, by linear combinations of basic functions, such as powers, exponentials, sigmoids, sines, and cosines in the position coordinates. Some difficulties rise in distinguishing the drift from the spatial correlated residuals, then in modeling the same drift. The intrinsic random functions of order k may be used to solve the problem when polynomial drift functions are

reasonable. Problems may also originate from relevant disparity in the variances at different locations. In this case, it is advisable to divide the spatial domain into more homogeneous regions or remove the outliers sites, if any.

One of the best approaches in extending the usual geostatistical tools to space-time domain is to treat time as another dimension. After that, spatial and temporal coordinates can be kept separate or can be used to introduce a metric into the higher dimensional space. However, since the units for space and time are disparate, e.g., meters and hours, one might ask if it makes any sense to define a spatio-temporal metric,

$$d(\mathbf{u}_1, \mathbf{u}_2) = \left[a(x_1 - x_2)^2 + b(y_1 - y_2)^2 + c(t_1 - t_2)^2 \right]^{1/2},$$

with $\mathbf{u}_1 = (x_1, y_1, t_1)$, $\mathbf{u}_2 = (x_2, y_2, t_2)$ where $(x_1, y_1), (x_2, y_2) \in D \subseteq \mathbb{R}^2$, and $t_1, t_2 \in T \subseteq \mathbb{R}$, where D and T are the spatial and temporal domains, respectively.

Basic Theoretical Framework

In the literature, geostatistical methods have been widely used to analyze spatial and, more recently, spatio-temporal processes in nearly all the areas of applied sciences and especially in Earth Sciences, such as Hydrogeology, to study the movement, distribution and management of water; Environmental engineering, to study concentrations of pollutants in different environmental media, water/air/soil; Meteorology for the analysis of variations in atmospheric temperature, density, and moisture contents. In these contexts, geostatistical tools are flexible enough to analyze the spatio-temporal evolution of a wide range of phenomena, where their spatio-temporal pattern presents a systematic structure at the macroscopic level and a random behavior at the microscopic level. For this reason, suitable stochastic models for spatio-temporal processes should be considered, and a theory of *STRFs* is needed in order to proceed with the rigorous mathematical modeling of processes that jointly change in space and time.

The observed values of a spatio-temporal process are considered as a finite realization of a *STRF* $\{Z(\mathbf{s}, t); \mathbf{s} \in D, t \in T\}$, where $D \subseteq \mathbb{R}^d$, $d \leq 3$, is the spatial domain and $T \subseteq \mathbb{R}_+$ is the temporal domain. The *STRF* Z can be decomposed as follows:

$$Z(\mathbf{s}, t) = \mu(\mathbf{s}, t) + Y(\mathbf{s}, t), \quad (1)$$

where $\mu(\mathbf{s}, t) = E[Z(\mathbf{s}, t)]$ represents a macro scale component, which can be nonconstant in space and time, and Y represents the residual stochastic component with $E[Y(\mathbf{s}, t)] = 0$, which describes the random fluctuations, around

μ , on a small scale. The mean, or deterministic component, $\mu(\cdot)$ is defined as a linear combination of linearly independent functions of the space-time coordinates; it is also called drift, while the term trend, erroneously associated to $\mu(\cdot)$, pertains to data not to the *STRF* model. Under second order stationarity hypothesis, the expected value of Z is assumed to be constant over the domain, i.e., $E[Z(\mathbf{s}, t)] = \mu$, and its second order moments, such as the spatio-temporal variogram and the covariance function, depend on the spatio-temporal lag $(\mathbf{h}_s, h_t)$, for any $(\mathbf{s}, t), (\mathbf{s}', t')$ in the spatio-temporal domain, with $\mathbf{h}_s = \mathbf{s} - \mathbf{s}'$ and $h_t = t - t'$. Then, given the hypothesis of second order stationarity, the spatio-temporal variogram and the covariance function are defined, respectively, as follows:

$$\gamma(\mathbf{h}_s, h_t) = 0.5E[Z(\mathbf{s}, t) - Z(\mathbf{s} + \mathbf{h}_s, t + h_t)]^2, \quad (2)$$

$$C(\mathbf{h}_s, h_t) = E[Z(\mathbf{s}, t)Z(\mathbf{s} + \mathbf{h}_s, t + h_t)] - \mu^2. \quad (3)$$

The variogram is a measure of dissimilarity, in the sense that it increases when the distance between $(\mathbf{s}, t)$ and $(\mathbf{s} + \mathbf{h}_s, t + h_t)$ increases; thus, it is usually characterized by small values for short distances in space and time. On the other hand, the covariance function is a measure of similarity, in the sense that it usually decreases when the distance between $(\mathbf{s}, t)$ and $(\mathbf{s} + \mathbf{h}_s, t + h_t)$ increases; thus, it is often characterized by high values for short distances in space and time. Note that the term covariogram is associated with the graphical representation of the covariance function. In a 2D domain, the covariogram is obtained through a Cartesian diagram, with the stationary covariance function on the vertical axis and the distance on the horizontal axis.

A space-time variogram function γ must be conditional negative definite, namely

$$\sum_{i=1}^n \sum_{j=1}^n a_i a_j \gamma(\mathbf{s}_i - \mathbf{s}_j, t_i - t_j) \leq 0, \quad (4)$$

for any $n \in \mathbb{N}_+$, any $(\mathbf{s}_i, t_i) \in D \times T$, where the coefficients $a_i \in \mathbb{R}$ respect the condition:

$$\sum_{i=1}^n a_i = 0. \quad (5)$$

The function γ is conditional strictly negative definite if the quadratic form in (4) is strictly less than zero for any $n \in \mathbb{N}_+$, any choice of distinct points $(\mathbf{s}_i, t_i)$, and any $a_i \in \mathbb{R}$, not all zero, under the condition (5).

Similarly the covariance function must be positive definite, namely:

$$\sum_{i=1}^n \sum_{j=1}^n a_i a_j C(\mathbf{s}_i - \mathbf{s}_j, t_i - t_j) \geq 0, \quad (6)$$

for any $n \in \mathbb{N}_+$, any $(\mathbf{s}_i, t_i) \in D \times T$ and any $a_i \in \mathbb{R}$. It is easy to show that given a linear combination of spatial-temporal random variables,

$$C = \sum_{i=1}^n a_i Z(\mathbf{s}_i, t_i),$$

the above conditions ensure the variance to be non-negative. The function C is strictly positive definite (SPD) if it is excluded the chance that the quadratic form in (6) is equal to zero for any choice of distinct points $(\mathbf{s}_i, t_i)$, $\forall a_i \in \mathbb{R}$ (with at least one different from zero) and $\forall n \in \mathbb{N}_+$. Note also that strict positive definiteness is desirable, since it ensures the invertibility of the kriging coefficient matrix (De Iaco and Posa 2018).

Given the difficulties to verify the conditions (4) and (6), it is advisable for users to look for the best model among the wide parametric families whose members are known to respect the above-mentioned admissibility conditions. It is worth highlighting that, although a number of studies provide theoretical results in terms of the covariance, the space-time correlation is usually analyzed through the variogram, which is preferred to the covariance for several reasons (Cressie and Grondona 1992).

A space-time geostatistical analysis can be carried out through the following steps:

1. Look for a model of the *STRF* from which data could reasonably be derived
2. Estimate the variogram or the covariogram, as a measure of the spatio-temporal correlation exhibited by the data
3. Fit a suitable model to the estimated variogram or covariogram;
4. Use this last model in the kriging system for spatio-temporal prediction.

Regarding the first point, it is common to use the model for the *STRF* given in (1), which can include a component μ and the stationary residual component Y . In presence of a non-constant component with large-scale variation, this is commonly estimated (e.g., through least squares regression) and removed from the observed data; then the spatio-temporal correlation analysis is conducted on the residuals, which can be reasonably assumed to be a realization of a second order stationary random field. After analyzing and modeling both components of model (1), predictions of the variable under study can be computed by adding the estimated drift to the predicted residuals, obtained through ordinary kriging.

Alternatively, other forms of kriging can be used in case of non-stationarity, as will be clarified in the section dedicated to prediction.

Structural Analysis

Structural analysis is executed on the spatio-temporal realizations of a second-order stationary random function. These realizations correspond directly to the observed values (if the macro scale component can be reasonably supposed constant over the domain) or to the residuals otherwise. The two steps in the structural analysis consist in estimating the space-time variogram or covariogram and fitting a model. Then, geostatistical analysis proceeds with model validation.

Sample Variogram and Covariogram

Under second order stationarity, structural analysis begins with the estimation of the space-time variogram or covariogram of the random function Z .

Given the set $A = \{(\mathbf{s}_i, t_i), i = 1, 2, \dots, n\}$ of data locations in space-time, the variogram can be estimated through the sample space-time variogram $\hat{\gamma}$ as follows:

$$\hat{\gamma}(\mathbf{r}_s, r_t) = \frac{1}{2|L(\mathbf{r}_s, r_t)|} \sum_{L(\mathbf{r}_s, r_t)} [Z(\mathbf{s} + \mathbf{h}_s, t + h_t) - Z(\mathbf{s}, t)]^2, \quad (7)$$

where $|L(\mathbf{r}_s, r_t)|$ is the cardinality of the set.

$L(\mathbf{r}_s, r_t) = \{(\mathbf{s} + \mathbf{h}_s, t + h_t) \in A, (\mathbf{s}, t) \in A : \mathbf{h}_s \in \text{Tot}(\mathbf{r}_s) \text{ and } h_t \in \text{Tot}(r_t)\}$, and $\text{Tot}(\mathbf{r}_s)$, $\text{Tot}(r_t)$ are, respectively, some specified tolerance regions around $\mathbf{r}_s$ and r_t . Similarly, the space-time sample covariogram $\hat{C}$ is defined as follows:

$$\hat{C}(\mathbf{r}_s, r_t) = \frac{1}{|L(\mathbf{r}_s, r_t)|} \sum_{L(\mathbf{r}_s, r_t)} [Z(\mathbf{s} + \mathbf{h}_s, t + h_t) - \mu][Z(\mathbf{s}, t) - \mu], \quad (8)$$

where μ is substituted by the sample mean $\bar{Z}$, if μ is an unknown constant. Note that the estimator of the space-time variogram is not influenced by the expected value μ or its estimator $\bar{Z}$ and is unbiased with respect to γ . It is important to underline that no space-time metric is needed for the computation of both estimators. In fact, the pairs of points separated by $(\mathbf{h}_s, h_t)$ are detected by computing, separately, the purely spatial and purely temporal distances; thus, the pairs of realizations, $z(\mathbf{s}, t)$ and $z(\mathbf{s} + \mathbf{h}_s, t + h_t)$, correspond to the observations at the points that are simultaneously separated by $\mathbf{h}_s$, in the space domain, and h_t , in the time domain.

Models for Variogram or Covariance Function

The second step of structural analysis consists in fitting a theoretical valid model to the sample space-time variogram or covariogram. Nowadays, various classes of space-time covariance functions or variograms are available, such as the metric class of models, the sum model, the product model, and a wide range of families of non-separable space-time models, such as the product-sum and its integrated version, the classes proposed by Cressie-Huang, Gneiting, Ma, and Porcu to cite a few (De Iaco et al. 2013):

- The Cressie-Huang class of models (Cressie and Huang 1999)

$$C(\mathbf{h}_s, h_t) = \int_{\mathbb{R}^d} e^{i\mathbf{h}_s^T \boldsymbol{\omega}} \rho(h_t; \boldsymbol{\omega}) k(\boldsymbol{\omega}) d\boldsymbol{\omega}, \quad (9)$$

where $\rho(\cdot; \boldsymbol{\omega})$ is a continuous integrable correlation function for all $\boldsymbol{\omega} \in \mathbb{R}^d$, and $k(\cdot)$ is a positive function, which is integrable on $\mathbb{R}^d$;

- The Gneiting class of models (Gneiting 2002)

$$C(\mathbf{h}_s, h_t) = \frac{\sigma^2}{[\psi(h_t^2)]^{d/2}} \phi\left(\frac{\|\mathbf{h}_s\|^2}{\psi(h_t^2)}\right), \quad (10)$$

where $\phi(t)$, $t \geq 0$, is a completely monotone function, $\psi(t)$, $t \geq 0$ is a positive function with completely monotone derivative and σ^2 is the variance;

- The Ma class of models (Ma 2002)

$$C(\mathbf{h}_s, h_t) = \sum_{k=0}^{\infty} \{C_S(\mathbf{h}_s)C_T(h_t)\}^k p_k, \quad (11)$$

where $C_S(\cdot)$ and $C_T(\cdot)$ are purely spatial and purely temporal covariance functions on D and T , respectively; $\{p_k, k \in \mathbb{N}\}$ is a discrete probability function;

- The Porcu, Mateu, and Gregori class (Porcu et al. 2007; Mateu et al. 2007)

$$C(\mathbf{h}_s, h_t) = \int_0^\infty \int_0^\infty \exp\left[-\sum_{i=1}^d \psi_i(|h_i|)v_1 - \psi_t(|h_t|)v_2\right] dF(v_1, v_2), \quad (12)$$

where F is a bivariate distribution function ψ_i and ψ_t are Bernstein functions (positive functions on $\mathbb{R}_+$ with completely monotone derivatives), with $\psi_i(0) = \psi_t(0) = 1$;

- The class of integrated models (De Iaco et al. 2002)

$$C(\mathbf{h}_s, h_t) = \int_V \left[k_1 C_S(\mathbf{h}_s; x) C_T(h_t; x) + k_2 C_S(\mathbf{h}_s; x) + k_3 C_T(h_t; x) \right] d\mu(x), \quad (13)$$

where $\mu(x)$ is a positive measure on $U \subseteq \mathbb{R}$, $C_S(\mathbf{h}_s; x)$ and $C_T(h_t; x)$ are covariance functions defined on $D \subseteq \mathbb{R}^d$ and $T \subseteq \mathbb{R}$, respectively, for all $x \in V \subseteq U$, $k_1 > 0$, $k_2, k_3 \geq 0$. If $k_2 = k_3 = 0$, the above class of models is called integrated product models; otherwise, it is called integrated product-sum models. As specified in the following, this class is very flexible, since it is able to describe all types of non-separability.

The choice of an appropriate class of models can be supported by testing the main properties (symmetry/asymmetry, separability/non-separability, type of non-separability) of the spatio-temporal sample variogram/covariance function (Cappello et al. 2018); the related computational aspects were developed in Cappello et al. (2020). Although the selection of a suitable class of models can be based on its geometric features and theoretical properties, in practice, the generalized product-sum model, thanks to its versatility, is largely used in different areas, ranging from environmental sciences to medicine and from ecology to hydrology. This last model, written in terms of variogram, has the following form:

$$\gamma(\mathbf{h}_s, h_t) = \gamma(\mathbf{h}_s, 0) + \gamma(\mathbf{0}, h_t) - k\gamma(\mathbf{h}_s, 0)\gamma(\mathbf{0}, h_t), \quad (14)$$

where $\gamma(\mathbf{h}_s, 0)$ and $\gamma(\mathbf{0}, h_t)$ are the spatial and temporal marginal variograms, respectively (De Iaco et al. 2001). The power of the model lies in the flexibility of the fitting process, which uses the sample marginals and only one parameter, which depends on the global sill (i.e., the space-time variogram upper bound). The parameter k is selected in such a way to ensure that the global sill is fitted. Admissible values for this parameter are dependent on the sill values of the spatial and temporal marginals $\gamma(\mathbf{h}_s, 0)$ and $\gamma(\mathbf{0}, h_t)$, as specified in De Iaco et al. (2001). Moreover, the generalized product-sum model enables modeling processes characterized by different variability along space and time.

Model Validation

After modeling the space-time empirical variogram/covariogram surface, the subsequent step is to evaluate the reliability of the fitted model through the application of spatio-temporal cross-validation and jackknife techniques. Then, if the model performance is satisfactory, the same model can be used to predict the variable under study over

the spatial domain and for future time points by space-time kriging.

Cross-validation allows a comparison to be made between estimated values and observed ones, simply using the sample information: the value measured at a fixed space-time point is temporarily removed, and at the same point, the value of the variable of interest is estimated by using all the other available values and the fitted space-time variogram/covariogram model. This process is repeated for all the sample points. Finally, statistical tools, such as the linear correlation coefficient between the observed values and the estimated ones, can be used to evaluate the goodness of the fitted model. In the jackknife technique, the variogram/covariogram model is used to estimate the variable under study measured at some points, which are usually not coincident with the original sample points. Then, the data available at the points, where the estimation is required, are compared with the estimated values. In other terms, the validation is based on a new data set, not previously used in the structural analysis and thus not considered in the construction of the covariance/variogram model to be validated.

Prediction

Geostatistical spatio-temporal prediction techniques can be viewed as an extension of the spatial ones. Indeed, given the observed data $\{z(\mathbf{u}_i) = z(\mathbf{s}, t), i = 1, \dots, n\}$, the problem is to predict $Z(\mathbf{u}) = Z(\mathbf{s}, t)$ at the unsampled space-time location $\mathbf{u} = (\mathbf{s}, t)$. For this aim, the following class of linear predictors is defined:

$$\hat{Z}(\mathbf{u}) = \sum_{i=1}^n \lambda_i(\mathbf{u}) Z(\mathbf{u}_i). \quad (15)$$

The weights $\lambda_i(\cdot)$, $i = 1, \dots, n$ are obtained, through the kriging methods, by requiring that (15) is unbiased and the mean squared prediction error is minimized. In particular, under the second-order stationarity, one can choose between simple kriging, if the expected value μ is constant and known, and ordinary kriging, if the expected value μ is constant and unknown. In this last case, the following linear system, often called *ordinary kriging system*, is obtained:

$$\begin{cases} \sum_{i=1}^n \lambda_i(\mathbf{u}) \gamma(\mathbf{u}_i - \mathbf{u}_j) - \omega(\mathbf{u}) = \gamma(\mathbf{u}_j - \mathbf{u}), j = 1, \dots, n, \\ \sum_{i=1}^n \lambda_i(\mathbf{u}) = 1, \end{cases} \quad (16)$$

where γ represents the space-time variogram of Z and ω is the Lagrange multiplier. The above system can be also expressed

in terms of a space-time covariance model. Note that the kriging system requires the knowledge of the space-time covariance/variogram model to be solved in terms of the weights $\lambda_i(\cdot)$, $i = 1, \dots, n$.

On the other hand, if the expected value of the random field Z is known, then the estimator of Z at the unsampled space-time location $\mathbf{u} = (\mathbf{s}, t)$ is equivalent to the estimator of the zero-mean random field Y at $\mathbf{u}$ and the weights $\lambda_i(\cdot)$, $i = 1, \dots, n$ are the solutions of the following linear system of n equations, called *simple kriging system*:

$$\sum_{i=1}^n \lambda_i(\mathbf{u}) \gamma(\mathbf{u}_i - \mathbf{u}_j) = \gamma(\mathbf{u}_j - \mathbf{u}), \quad j = 1, \dots, n, \quad (17)$$

This systems has a unique solution if the coefficient matrix (or the variogram/covariogram matrix) is non-singular, and this is guaranteed if and only if the covariance function is strictly positive definite (or the variogram is conditionally strictly negative definite) and if all sample points are distinct. Note that the simple and ordinary kriging are free-distribution predictors and are considered to be the “best” because they minimize the estimation variance among all the linear unbiased estimators. In case of a Gaussian random field, the simple kriging predictor coincides with the conditional expectation $E(Z | Z_1, \dots, Z_n)$, thus it is the best estimator of Z in the mean square sense.

Moreover, if the unknown expected value cannot be assumed to be constant, the drift can be modeled (even by using external variables) and removed, then the above stochastic methods for spatio-temporal prediction can be proposed for the residuals. If the expected value of the random function can be expressed in a polynomial functional form, kriging with a trend model, known as universal kriging, can be applied. Alternatively, the intrinsic random functions of order k , introduced by Matheron (1973), can be also considered; in this case the drift component is interpreted as a deterministic component, modeled with local polynomial forms. In both options, these kriging predictors can be built to have minimum error variance subject to the unbiasedness constraint.

Computational Aspects

Spatio-temporal data analysis can be supported by using various packages, such as the ones in the R programming language. Among these, it is worth mentioning the package space-time (Pebesma 2012) for dealing with spatio-temporal data, the package gstat for geostatistical modelling and interpolation (Gräler et al. 2016), where different choices of spatio-temporal covariance models have been implemented, such as the separable, product-sum, metric, and sum-metric

models. In addition, the R package RandomFields (Schlather et al. 2015) supports kriging, conditional simulation, covariance functions, and maximum likelihood function fitting for a wide range of spatio-temporal covariance models. Padoan and Bevilacqua (2015) built the R package CompRandFld for the analysis of spatial and spatio-temporal Gaussian and binary data, and spatial extremes through composite likelihood inferential methods. A more complete list of R packages related to spatio-temporal topics is available on CRAN Task Views “SpatioTemporal” (Pebesma 2020). Other contributions concern specialized routines and packages which perform spatio-temporal geostatistical analysis (De Cesare et al. 2002). The package covatest can help to cope with the problem of selecting a suitable class of space-time covariance functions for a given data set (Cappello et al. 2020).

Key Research Findings

Major applications of spatio-temporal modeling and kriging continue to be found in Earth Sciences, Engineering, Mining as well as in Environmental Health and Biodiversity. Specific case studies along these lines are too numerous to be mentioned here, and thus interested readers are invited to consult some recent review books (Montero et al. 2015) for more details. Rather we provide a brief overview of a selected number of key research findings with regards to recent contributions on some properties (such as symmetry/asymmetry, separability/non-separability, type of non-separability) of the space-time covariance functions (Gneiting et al. 2007; De Iaco et al. 2019; Cappello et al. 2020), which can support the model selection. Indeed, one might look for the class of models whose properties are consistent with respect to the characteristics of the empirical space-time covariance surface estimated from the data. For this reason, as clarified in De Iaco et al. (2013), finding an answer to the following questions is essential: (a) How do the spatial and/or the temporal variogram/covariance marginals behave at the origin? (b) Does the space-time data set present different variability along space and time? (c) Which kind of spatial anisotropy is required by the data? (d) Is there a space-time interaction? (e) Is the empirical space-time variogram/covariance function fully symmetric?

Anisotropy in Space-Time

A covariance function is said to be anisotropic in space if at least two directional spatial covariance functions differ. In the classical literature, two types of anisotropy are usually defined: the first type is the *geometric anisotropy*, which is associated with an isotropic covariance function where the coordinates are linearly transformed; the second one is the

stratified or zonal anisotropy, which is associated with the sum of covariance models on factor spaces.

Space and time cannot be directly comparable: hence, the definition of isotropy has no meaning for *STRFs*, although several textbooks and papers have tried to provide a definition of isotropy or geometric anisotropy in this context. An attempt to introduce a geometric anisotropy in space-time was given with the metric covariance model, where the spatial and temporal distances, h_s and h_t , are re-scaled through the use of appropriate spatial and temporal ranges, a_s and a_t , so that the terms h_s/a_s and h_t/a_t are a -dimensional. This allows to work with spatial and temporal coordinates with different physical dimensions (and units). In some cases (diffusion and transport processes), this anisotropy might describe rather well the reality, but the main problem is how to reasonably define the scale parameters on the basis of a physical interpretation. It is also worth highlighting that a second order stationary *STRF* Z , defined on $\mathbb{R}^d \times \mathbb{R}$, is said to be *spatially isotropic* in the weak sense, if its covariance function is such that

$$C_{WT}(\mathbf{h}_s, h_t) = C(\|\mathbf{h}_s\|, |h_t|). \quad (18)$$

On the other hand, the zonal anisotropic models can be built as the sum of different covariance models, each defined on different subspaces of the spatio-temporal domain. For example, zonal anisotropic covariance functions in a space-time domain $\mathbb{R}^d \times \mathbb{R}$ can be expressed as sum of spatial and temporal covariance models C_S and C_t as follows:

$$C(\mathbf{h}_s, h_t) = C_S(\mathbf{h}_s) + C_T(h_t),$$

where $\mathbf{h}_s \in \mathbb{R}^d$ and $h_t \in \mathbb{R}$. However, such models can lead to non-invertible kriging matrices, i.e., even though C_S and C_t are each SPD on the respective subspaces, their sum is only positive definite on the higher dimensional space (Myers and Journel 1990). Thus, an alternative zonal anisotropic covariance model can be obtained by summing to a weak isotropic component, as in (18), another component which can be a purely spatial covariance function, i.e.,

$$C(\mathbf{h}_s, h_t) = C_{WT}(\|\mathbf{h}_s\|, |h_t|) + C_S(\mathbf{h}_s).$$

In the spatio-temporal literature, various classes of stationary non-separable covariance functions with spatial anisotropy are available (Porcu et al. 2006).

Separability

The *STRF* Z on $\mathbb{R}^d \times \mathbb{R}$ is said to have a space-time separable covariance, if it can be written as the product of a purely

spatial covariance function C_S and a purely temporal covariance function C_T , defined on $\mathbb{R}^d$ and $\mathbb{R}$, respectively, i.e.,

$$C(\mathbf{h}_s, h_t) = C_S(\mathbf{h}_s)C_T(h_t), \quad (19)$$

or equivalently

$$C(\mathbf{h}_s, h_t) = \frac{C(\mathbf{h}_s, 0)C(0, h_t)}{C(0, 0)}, \quad (20)$$

where $\mathbf{h}_s \in \mathbb{R}^d$ and $h_t \in \mathbb{R}$. This implies that there is no interaction in space-time. It is clear that the above-mentioned spatio-temporal separability is essentially a partial separability. In case of non-separability, another interesting aspect concerns the type of non-separability, that is: *pointwise* or *uniform* and positive or negative (De Iaco and Posa 2013). The type of non-separability can be easily detected by computing, for each lag, the ratio between the empirical space-time covariance and the product of the sample spatial and temporal covariance marginals $\hat{C}(\mathbf{h}_s, 0)$ and $\hat{C}(0, h_t)$, if these last are positive. Indeed, if the sample ratio is overall greater (less) than 1, uniformly positive (negative) non-separable covariance classes are required. On the other hand, if the sample ratio is greater (less) than 1 for some lags and it is less (greater) than 1 for other lags, space-time covariance classes which are non-uniformly non-separable should be considered. Regarding this aspect, a very flexible class of models is the integrated family given in (13), since *pointwise* or *uniform* positive/negative non-separable models can be derived from it.

Symmetry

Given a stationary space-time covariance function, it is fully symmetric if

$$\begin{aligned} C(\mathbf{h}_s, h_t) &= C(-\mathbf{h}_s, h_t) = C(\mathbf{h}_s, -h_t) \\ &= C(-\mathbf{h}_s, -h_t), \quad \forall (\mathbf{h}_s, h_t) \in \mathbb{R}^d \times \mathbb{R}. \end{aligned} \quad (21)$$

Full symmetry can be an unrealistic assumption for space-time covariance functions encountered in many cases when there is a dominant flow direction over time (for example, in atmospheric processes). Note that the definition of *full symmetry* for a space-time covariance function corresponds to the definition of *reflection or axial symmetry* on $\mathbb{R}^2$. Although the two definitions are referred to different domains, in both cases the domains are partitioned into two factor domains (i.e., $\mathbb{R} \times \mathbb{R}$ or $\mathbb{R}^d \times \mathbb{R}$). Taking into account the above definitions, it is important to point out that symmetry properties represent weaker hypotheses than isotropy, since isotropy requires that C is only a function of the norm of the lag vector. Isotropic covariance functions are a subset of symmetric

covariance functions, thus methods for testing isotropy can be often used to test symmetry properties. Note that the definitions of strict positive definiteness, symmetry, and separability can be given for *STRFs*, without assuming any form of stationarity. On the other hand, the definition of isotropy is appropriate only for second order stationary spatial random functions on $\mathbb{R}^d$ and can be extended to a space-time context only in a weak sense.

Figure 1 offers a graphical representation on relations among separability, symmetry, isotropy, and SPD condition for stationary random functions in space-time. Assuming full symmetry is equivalent to axial symmetry with respect to the temporal axis, and separability between space and time is equivalent of introducing a partial separability. Regarding isotropy, a spatio-temporal random function is said spatially isotropic in the weak sense, if condition (18) is satisfied. Thus, in a space-time context, it is worth pointing out that isotropy, as in (18), or partial separability, as in (19), implies axial (or full) symmetry, as in (21), the converse is not true. A covariance model can be isotropic and separable if and only if all the factors of the product model are Gaussian covariance functions (gray areas in Fig. 1), as clarified in De Iaco et al. (2020). Strict positive definiteness is also a transverse characteristic among the other mentioned properties (De Iaco and Posa 2018).

Conclusions

At the end, it is worth pointing out that nowadays there are important areas of research that involve random functions in space-time (Porcu et al. 2012) and relevant computational challenges that involve big spatial and spatiotemporal data sets. Some significant lines of research can be found in:

- Multivariate spatio-temporal analysis which includes methods for modeling, predicting and simulating two or

Spatiotemporal, Fig. 1 Relationships among some common second-order properties for spatio-temporal covariance functions (gray areas represent the class of Gaussian covariance functions)

more variables in space and time (Apanasovich and Genton 2010; Genton and Kleiber 2015; Cappello et al. 2022b)

- Complex-valued random functions which have applications in modeling wind fields, sea currents, electromagnetic fields (Posa 2020, 2021; De Iaco 2022; Cappello et al. 2022a)
- Bayesian methods which are gaining popularity both in spatial and spatio-temporal statistics and in physics (Diggle and Ribeiro 2007; Xu et al. 2015; Gelfand and Banerjee 2017)
- Machine learning methods developed by the computational science researchers which can also be applied to spatio-temporal data (Hristopoulos 2015; McKinley and Atkinson 2020; De Iaco et al. 2022)
- Modeling a spatio-temporal random field that has non-stationary covariance structure in both space and time domains (Porcu 2007; Zimmerman and Stein 2010; Shand and Li 2017)
- Parametric covariance modeling techniques for space-time processes, where space is the sphere representing our planet (Jun and Stein 2012; Porcu et al. 2016, 2018)

Most of the modeling advances have been contributing to face interpolation or prediction problems, perform stochastic simulation, and deal with classification issues.

In conclusion, this scientific field has been very active in the last 30 years, as confirmed by the extensive literature and the dedicated sessions in worldwide conferences, and still presents broad margins of progress.

Definition

The trace gases are those constituents of the atmosphere that exist in very small amounts, in total approximately around 0.1% of the atmosphere. Many common trace gases, such as water vapor, carbon dioxide (CO₂), methane (CH₄), and ozone (O₃), are the greenhouse gases (GHGs) which are increasing rapidly in Earth's atmosphere due to anthropogenic activity, therefore raising significant attention for its measurement and analysis. On the other hand, nitrogen dioxide (NO₂) is not a GHG but is important for the formation of tropospheric ozone, therefore indirectly contributing to the GHG concentration hike. The main sources of NO₂ are cars, trucks, power plants, and other industrial facilities that are burning fossil fuels (How to Find and Visualize 2021). The gas in high concentration can cause serious issues in the human respiratory system, even exposure over a short time may cause difficulty in breathing, aggravate respiratory diseases, particularly asthma, etc. In this chapter, a brief overview of spatio-temporal analysis of a few atmospheric trace gases is discussed with the inclusion in the recent developments of their remote sensing-based measurements. In particular, the applications of visualization, validation of trace gas measurements, and different analysis methods, such as prediction for missing data, atmospheric transport modeling, inverse modeling, machine learning, etc., are presented. Their spatiotemporal analysis leads to a broad spectrum of applications. Different analysis approaches are discussed in association with the recent investigations of three common atmospheric trace gases, CO₂, CH₄, and NO₂.

Remote Sensing-based Measurement of the Trace Gases

Many satellites are currently observing the atmospheric trace gas concentrations, mainly the GHGs and air pollutants, and measuring their spatiotemporal concentration data across the globe. Examples include the Orbiting Carbon Observatory-2 (OCO-2) (Crisp 2015) from NASA launched in 2014, and its successor OCO-3 (Eldering et al. 2019) which mainly estimates the column-averaged dry-air mole fraction of carbon dioxide (XCO₂). Another complementary example is the Sentinel 5p satellite (Judd et al. 2020), the TROPOMI spectrometer of which estimates many trace gases, including O₃, CH₄, CO, NO₂, sulphur dioxide (SO₂), etc. and aerosols in the atmosphere. These spectrometers on board the satellite are measuring the emitted or reflected radiation from the Earth, to extract different parameters related to the Earth's surface and atmosphere. The satellite retrievals are not the direct measurements; the instruments on satellites are measuring electromagnetic energy radiating from the Earth and atmosphere, which gets converted into geophysical parameters. Due to

great achievements in enhancing measurement techniques and instruments aboard, it is possible to gain better resolutions in time and space of satellite-borne trace gas data. A good example of this can be seen by comparing the Dutch-Finnish Ozone Monitoring Instrument (OMI) on the NASA Aura spacecraft in 2004 having a spatial resolution of $13 \text{ km} \times 24 \text{ km}$ at nadir, and its successor, the Tropospheric Monitoring Instrument (TROPOMI) on the satellite Sentinel 5p, launched by ESA in 2017, having a spatial resolution of $3.5 \text{ km} \times 5.5 \text{ km}$ approximately at nadir (Judd et al. 2020). Besides good improvements in the spatial resolution, the temporal resolution of satellites generally ranges between 1 – 16 days, depending on the orbit, the sensor's characteristics, and the swath width (What is Remote Sensing? 2022). In the case of the OCO-2 satellite, the temporal resolution is 16 days, which means that a huge portion of the Earth is unmeasured in a particular day. Whereas the Sentinel 5P provides the daily global coverage. The other well-known satellites for the trace gas measurements are the Exploratory Satellite for Atmospheric CO₂ (TanSat), Japanese Greenhouse Gases Observing SATellite (GOSAT), Greenhouse Gas Satellite-Demonstrator (GHGSat-D), etc.

Combining all of the desirable features into a single remote sensor is very difficult and there are trade-offs. To acquire observations with high spatial resolution, a narrower swath is required, which requires more time between observations of a given area, causing lower temporal resolution (What is Remote Sensing? 2022). Further, the missing data are preventing a complete understanding of the global cycles of trace gases, mechanisms that control their spatial and temporal variability, and other important features (Bhattacharjee and Chen 2020). In order to get the full picture of the Earth's atmospheric conditions, trace gases, and analyze them for different applications, spatiotemporal methods need to be applied to the collected data. An appropriate spatiotemporal analysis is necessary to learn about the current atmospheric trace gas conditions and to tackle global climate change by developing innovative techniques according to the observed data. A brief overview of the spatiotemporal analysis, including a few applications and methods, applied in the field of remote sensing of trace gases, will be discussed in the next section.

Spatiotemporal Analysis

Many applications and methods of spatiotemporal data analysis have been reported for satellite-borne trace gas data. These can be broadly categorized depending on their research and application objectives. In this entry, mainly three broad analysis approaches for different research objectives are described in brief, the spatiotemporal characteristics by visualization, validation of remotely-sensed trace gas data, as well as important methods of analyzing trace gases. Other research

objectives could be spatiotemporal decision-making, prediction, inversion, etc., hence the abovementioned ones are not exhaustive for the remotely-sensed trace gas data.

Visualization

Visualization plays a central role in the process of spatiotemporal analysis of trace gases and can be considered as one of the initial steps for further analysis. Some practical uses of the visualizations are detecting emission point sources of the trace gases, like power plants or tar sand, and monitoring changes in pollution over time due to anthropogenic activities, climate change policies, and regulations. A recent example is the measured reduction of NO₂ in early 2020 with NASA's satellite Aura in 2020 over China. The NO₂ values were 10 – 30% lower than the normal range observed for this time period, which can be partly attributed to the economic slowdown after the coronavirus outbreak (How to Find and Visualize 2021). Any temporal window can be chosen to visualize and compare the trace gas concentrations depending on the need of the applications. For example, a temporal window of 1 day is chosen in Fig. 1 and the NO₂ concentration data of two consecutive days of April 28 and 29, 2021, measured by TROPOMI, are shown here around the harbor in Bremerhaven, Germany. It is clearly seen that there is a burst in the NO₂ concentration in the lower-left corner which is mostly caused by the nearby power plant in Wilhelmshaven and is subjected to further investigations. ESA's TROPOMI is estimating the tropospheric column density of NO₂ in molec/cm². It is not feasible to measure surface NO₂ with the current satellite instruments, but it is possible to estimate tropospheric NO₂ vertical column density, which correlates well with the values on the surface in industrialized regions. Both databases of TROPOMI and OMI NO₂ data can be accessed via Earthdata Search (2021), typically in hierarchical data format. With the freely available tool Panoply from NASA, this data can be easily explored and visualized. Another possible way to explore the NO₂ data is delivered by the application called Giovanni. The data can be viewed as a seasonal or time-averaged map, scatter plot, or as a time-series for the chosen temporal window. Similarly, another tool to visualize the global carbon cycle is the Global Carbon Atlas, established by the Global Carbon Project (Global Carbon Atlas 2021). It provides the estimates of the emission generated from the natural processes and anthropogenic activities and updates the database annually. Pulse GHGSat (2021) is a visualization tool to check global methane concentrations around the world, established by GHGSat. It is updated weekly and shows monthly concentrations, averaged with the resolution of $2 \text{ km} \times 2 \text{ km}$ over land.

Validation of Datasets

After the launch of a satellite, the instruments onboard have to be recalibrated regularly to make sure that they are providing

Spatiotemporal Analysis,

Fig. 1 The two images are illustrated with the measurement of TROPOMI's column-averaged NO_2 on April 28 (LHS image 1) and 29, 2021 (RHS image 2), respectively, in the region around the harbor in Bremerhaven, Germany. The second image shows a burst in the NO_2 measurements in the lower-left corner which is mostly caused by the nearby power plant and subjected to further investigations

accurate measurements. Complete and accurate satellite measurements of the trace gases are heavily influenced by the poor signal-to-noise ratio and dense cloud cover over the observed area, in consequence of which missing/erroneous measurements can be found in some locations. It is not possible to directly measure the near-surface concentrations below the clouds. There are bad weather conditions, faults in the sensors, or several other factors, due to which the uncertainty of the remotely-sensed trace gas measurement can be high. As rightly pointed out by Loew et al. (Loew et al. 2017), the uncertainties present in the satellite data are the known unknown. Further, for the general quality assurance purposes also, validation is an integral part of the satellite measurements. The spatiotemporal validation process of the remotely-sensed trace gases is typically based on a comparison with more reliable ground-based networks. In (Verhoelst et al. 2021), Sentinel 5p TROPOMI's first 2 years' NO_2 measurements are validated against multiple ground-based instruments worldwide, such as Multi-Axis DOAS, NDACC Zenith-Scattered-Light DOAS, and 25 PGN/Pandora instruments. Another example is the Total Column Observing Network (TCCON), which is a global network of ground-based Fourier transform spectrometers. It provides accurate measurements of different trace gases, such as CO_2 , CH_4 , and others (Hardwick and Graven 2016). The instruments of TCCON offer a spectral resolution of 0.02 cm^{-1} and temporal resolution of about 90s. Another global network for GHG measurements was started by Karlsruhe Institute of Technology, Germany, using the EM27/SUN spectrometer, named as COCCON (Frey et al. 2019). A similar ground-based urban GHG network (MUCCnet) was established in 2019 by the Technical University of Munich, Germany, which consists of five fully automated and highly

precise Fourier-transform infrared spectroscopy (FTIR) monitoring systems, distributed in and around the city of Munich (Dietrich et al. 2021). It measures the column concentrations of CO_2 , CH_4 , and CO throughout the year by using the sun as light source. Such local networks are essential in providing more reliable ground-based measurements for local/regional level validation and general calibration applied to the satellite instruments.

Spatiotemporal Analysis Methods

A brief overview of the common methods applied for different applications is presented here. The geostatistical interpolation methods like kriging and many of its variants, such as simple kriging, ordinary kriging, universal kriging, spatial block kriging, fixed rank kriging, etc., can be applied for predicting missing data, that occur due to cloud cover, poor signal due to bad weather conditions, etc. (Bhattacharjee et al. 2013). A recent work (Bhattacharjee and Chen 2020) has analyzed and made use of the trace gas emission estimates, which in turn contributes to their atmospheric concentrations. It has adopted the multivariate interpolation method to predict local column-averaged CO_2 distribution by combining the auxiliary emission estimates and land use/land cover distribution of the study areas. As mentioned before, the prediction results are validated against the TCCON data.

Wind is having a significant influence on the atmospheric transport pattern of the trace gases (Zhao et al. 2019), and these local spatiotemporal processes in turn have a high impact on the atmospheric concentrations of trace gases like CO_2 . Wind develops as a result of spatial differences in atmospheric pressure, which occurs at sea-land transitions due to the uneven absorption of solar radiation (Jacob 1999). The rapidly changing wind speed and wind directions

can only be taken properly into account when the scope of the spatiotemporal analysis changes into a smaller time period. Anthropogenic CO₂ emissions are perturbing the natural balance of CO₂ and causing its atmospheric concentration to rise. The emitted particles of CO₂ get transported by the wind from one place to another, which can change the concentration in a particular location, depending on the wind speed and direction. Therefore, we should take the wind information into account for short-term spatiotemporal analysis. One way to incorporate this information is to use the footprint information, which can be created using the Lagrangian particle dispersion model (LPDM) driven by meteorology models. In combination with surface fluxes, it is possible to determine concentration changes at any region (Bhattacharjee et al. 2020). Similarly, the high-resolution Weather Research and Forecasting model, in combination with GHG modules (WRF-GHG), can model precise meso-scale atmospheric GHG transport, especially in urban areas. In (Zhao et al. 2019), the WRF-GHG model is implemented to simulate the photosynthetic activity of vegetation, emission, and transport of CO₂ and CH₄ in the city of Berlin in 1 km resolution.

Inverse analysis (Jacob et al. 2016) is another important and widely used approach for flux inversion to understand the source and sink distribution at the Earth's surface. The basic idea is to combine global atmospheric transport models with trace gas concentration measurements for estimating the relationship between flux and tracer distributions with different inverse techniques, such as Bayesian inversion, adjoint approach, Markov Chain Monte Carlo (MCMC), etc. The accuracy of the inverse modeling technique depends on the quality of the transport field, the prior flux information used, etc. Many studies have used satellite observations for flux inversion to facilitate modeling very large atmospheric datasets. The inversion technique has been widely applied for CO₂, CH₄, NO₂, and other trace gas measurements from different satellite observations including OCO-2, GOSAT, Sentinel-5P, etc.

Finally, different machine learning approaches are also currently being used for the spatiotemporal analysis of trace gases for different applications. In (Lary et al. 2018), the potential of the machine learning methods for the mandatory bias correction and cross-calibration of the measurement instruments is discussed. Studies are reported to infer the CO₂ flux over land region using an LSTM recurrent neural network using OCO-2 data combined with CO₂ flux tower data (Nguyen and Halem 2018). Machine learning classifiers are being used to identify bad pixels from the satellite measurements (Marchetti et al. 2019), to estimate surface concentration from the vertical column densities (Chan et al. 2021), etc.

Summary or Conclusions

Several aspects of spatiotemporal analysis of trace gases have been discussed, including visualization, validation, and different spatiotemporal analysis methods, such as missing data handling, atmospheric transport modeling, inverse modeling, machine learning methods, etc. Each one of them explores the characteristics of atmospheric trace gases like CO₂, CH₄, NO₂, etc., in different application domains and help to understand the global and local atmospheric processes worldwide. Satellite-borne trace gas data, combined with various ground-based monitoring networks, are the foundation that enables a broad spectrum of their spatiotemporal analysis. Different investigations around the globe have been mentioned here in order to show traditional methods for the spatiotemporal analysis of trace gases and investigate the recent extensions created with data fusion approaches in the future. Though the discussion is not exhaustive, it gives the initial pointers for further exploration.

Definition

Spatiotemporal modeling covers a broad spectrum of algorithms dealing with spatiotemporal data and a wide range of applications in many fields. The generic idea behind these modeling approaches is to analyze the temporal pattern of target variables within a spatial domain of interest. Therefore, it is needless to say that such modeling approaches are usually complex in nature due to heterogeneous behavior in space and time domains, diverse and voluminous data to deal with, the associated uncertainties, etc. These models can be used for different purposes, such as estimation or prediction, spatiotemporal trend analysis, pattern recognition, and more. In this chapter, we have discussed some applications in the area of environmental data analytics and the spatiotemporal modeling approaches. We further discuss spatiotemporal outlier detection approaches, taking it as a case study, as it is one of the basic data-preprocessing approaches applied in several spatiotemporal analyses. These models can help detect anomalies present in the data which changes over time as well as space, hotspot detection, and understanding their effects on different applications.

Introduction

With the ongoing trend toward big data and growing computational abilities, the prior computational limits of complex spatiotemporal analysis are being narrowed down further. New spatiotemporal approaches are investigated which are upgrading the strong foundations of well-established spatiotemporal analysis methods. The new possibilities are targeting many research areas that can be very different, widely spread, and of current interests, but must address the challenge of spatial data modeling that changes over time. Among many applications of spatiotemporal data modeling,

one significant example can be investigating geospatial processes on our planet Earth.

Geospatial data is a good example of spatiotemporal data. It changes with time as well as space, and some changes even might span centuries. There are many initiatives on a global scale to capture and monitor geospatial data in many forms. Satellite missions have been measuring geospatial environmental variables, for example, TIROS-1, launched by NASA in 1960 (Schnapf 1982), is considered to be the first successful weather satellite. Modeling these data has been an area of interest for a long time, mainly due to the global problem of climate change, global warming, and related subproblems. Geospatial data usually comes with spatial and temporal uncertainties due to the difficulty of capturing it. Therefore, once this data has been captured, it needs to be processed to remove erroneous readings and converted into data products. These data products are then used for modeling to infer implicit patterns. One of the major data-preprocessing stages that could be involved in any modeling processes is the outlier detection.

Outliers can reveal significant information regarding the datasets and the applications. As these are the points that do not follow a specific pattern or are highly isolated from similar data points, investigating the reason behind these points being outliers can lead us to infer important conclusions about the specific problem domain. For example, outliers can reveal information about hotspots, coldspots, or any other point sources of the target variables. Here, the spatiotemporal modeling approaches and its characteristics, one application domain, one modeling approach, i.e., the outlier detection method in general, and a few algorithms for the spatiotemporal outlier detection are discussed.

Spatiotemporal Modeling

Spatiotemporal modeling covers a broad spectrum of approaches and can include different research objectives. It refers to methodological formalization, which will accurately describe the behavior of a certain set of target variables that vary over space and time. The research and application objectives of spatiotemporal modeling can include multiple aspects as follows (Song et al. 2017):

- Description of spatiotemporal characteristics
- Exploration of potential features and spatiotemporal prediction
- Modeling and simulation of spatiotemporal processes
- Spatiotemporal decision-making

Similarly, many models are associated with the abovementioned objectives. For example, models such as spatiotemporal kriging build variogram models that describes

underlying spatiotemporal characteristics of the data. Similarly, Bayesian Maximum Entropy (BME) model (Christakos and Li 1998) can be used for incorporating prior information in case of limited data availability. Various types of regression models, such as spatiotemporal multiple regression, geographically and temporally weighted regression (GTWR), spatiotemporal Bayes hierarchical model (BHM), etc., are used for exploring potential factors and spatiotemporal prediction. On the other hand, popular modeling and simulation models include cellular automaton (CA) and the geographical agent-based model (ABM).

Spatiotemporal decision-making processes use models such as the spatiotemporal multicriteria decision-making model (MCDM).

Applications of Spatiotemporal Modeling

These abovementioned objectives of the spatiotemporal modeling approaches are common for a wide range of applications. For example, the analysis and modeling of meteorological and atmospheric data, which falls under the broad spectrum of environmental applications, have implemented these models for different applications.

In Qin et al. (2017), the geographically and temporally weighted regression (GTWR) model has been considered for predicting ground-level concentration of NO₂ over central-eastern China, based on tropospheric NO₂ columns provided by the Ozone Monitoring Instrument (OMI) combined with ambient monitoring station measurements and meteorological data. The approach showed better or comparable performance with respect to chemistry-based transport models. It is also observed that the people from densely populated areas are more prone to be affected by high NO₂ pollution. Another application for spatiotemporal modeling can be found within the prediction of wildfire propagation and extinction, as shown in Clarke et al. (1994). According to Pechony and Shindell (2010), global fire activity is increasing and there are indications that the future climate will be the deciding factor of global fire trends, compared to the direct human intervention effects on the wildfires. Clarke *et al.* (Clarke et al. 1994) have used a cellular automaton model with additional environmental data, such as wind speed and magnitude, in order to predict the behavior of wildfire and how it will expand. On the other hand, for estimating the sparse column-averaged dry-air mole fraction of carbon dioxide (XCO₂) measured by the Orbiting Carbon Observatory-2 (OCO-2) satellite, kriging-based spatiotemporal and cokriging-based spatial interpolation have been used for generating a Level-3 XCO₂ mapping (Bhattacharjee et al. 2020; Bhattacharjee and Chen 2020). The used method combined the satellite-borne data with auxiliary emission data and land use land cover data, which enhanced the prediction accuracy of XCO₂. Lee

et al. (2018) have proposed an approach using support vector regression for predicting the weather station observations from a spatial perspective. Excluding potential measurement errors within the observations of automatic weather stations is important for increasing the quality of the meteorological observations and for further weather forecasting, disaster warning, or policy formulations. In this manuscript, all abnormal data points will be detected and excluded based on the difference between their actual and estimated values. Marchetti et al. (2019) have presented a machine-learning approach to identify the damaged or unusable pixels in the focal plane array (FPA) of NASA's OCO-2 and Orbiting Carbon Observatory-3 (OCO-3). This task is mainly challenging because of the voluminous data and the diversity of anomalous behavior. Therefore, identifying abnormal factors or data points to increase the accuracy of the measurements or to identify the hotspots is one of the crucial tasks in the field of spatiotemporal modeling. In the next section, the spatiotemporal outlier detection methods and related algorithms are discussed as a representative of widely used methods in spatiotemporal applications.

Spatiotemporal Outlier Detection Method

A spatial outlier is a data point or an object whose nonspatial attribute values are distinctly different from its neighboring data points. A point can be an outlier for a certain neighborhood even if it is typical considering the entire population. Based on these backgrounds, in statistics and data science, the three common categorizations of the outliers (in general) are *global*, *contextual*, and *collective* outliers (Han et al. 2012). When a data point or an object is significantly different compared to the entire sample population, is referred to as the global outlier. On the other hand, the data point deviations given a selected context are the contextual outliers. For example, a high greenhouse gas concentration may be typical for an industrial area, but could be a hotspot for a vegetation cover. The collective outliers are a subset of data points if they significantly deviate from the entire population as a group, but not individually in a global or contextual sense. The same

definition can be extended for spatiotemporal outliers. In the case of spatial and spatiotemporal outliers, the difference exists in defining the *neighborhood*. For a spatial outlier, the neighborhood is the set of points within a certain distance of the point under consideration at a single timestamp, whereas, spatiotemporal outliers are data points which exhibit abnormal behavior within a region of interest at some timestamps over a consecutive period (Cheng and Li 2006). Checking and identifying the anomalous points in both spatial and/or time-temporal dimensions makes the spatiotemporal outlier detection approaches more complex compared to purely spatial or temporal outlier detection.

A sample point might seem like an outlier at a certain timestamp (spatial outlier) but may not actually be one in a spatiotemporal context. For example, in the below map of a region with nine pixels, the distribution of a variable *land use land cover* at different timestamps is shown (Anbaroglu 2009). At time T_i , the vegetation (green) pixel in the middle might be an outlier compared to the surrounding built-up area pixels (yellow), and are subjected to further investigations. However, if future timestamps are considered, it is realized that the vegetation is growing and forming a pattern temporally, hence not a spatiotemporal outlier considering four timestamps.

According to Agarwal et al. (2017), the spatiotemporal outliers can be detected in two possible ways:

- Combining the spatial and temporal outliers that are found in two separate processes
- Using both the spatial (for example, latitude, longitude, etc.) and temporal (for example, timestamp) attributes as contextual attributes and find the outliers

The authors have mentioned that the second approach is more *general*, *integrated*, and *flexible* because both spatial and temporal locality can be used to detect the outlier and both the dimensions can be weighed differently based on the application requirement. However, depending on the applications and the datasets used, either of the methods can produce the best results.

Spatiotemporal Modeling, Fig. 1 The change/growing of “vegetation” (green) pixel over the time

Spatiotemporal Outlier Detection Algorithms

The algorithm used to detect spatiotemporal outliers varies from one use case to another as it highly depends on applications, temporal frequency of data collection, number of available timestamps, size of the study region, etc. Some spatiotemporal outlier detection algorithms, used in different literature, will be discussed as follows.

Cheng and Li (Cheng and Li 2006) propose a multiscale technique for spatiotemporal outlier detection. In the preliminary stage of the approach, spatiotemporal objects are classified into clusters using some clustering algorithms adapted to the characteristics of the data. Then, in the second phase, more spatiotemporal objects are aggregated in each cluster by increasing the window or scale of the cluster. An object, which was not classified into any cluster before might be assigned to one now, and objects might change clusters as well. This step is followed by a comparison of the results within the first and the second phases to detect potential spatial outliers. Finally, the potential spatial outliers will be observed over multiple time periods via human observations. If they show consistent behavior over time, they are no longer considered as the outliers. The remaining set of objects is then concluded to be spatiotemporal outliers. This method is more suitable for large geographical data with a very low temporal frequency. As the final phase is carried out by human observations, too many frames or maps will make it difficult to identify patterns or trends. In the manuscript, the authors have used a dataset with a temporal frequency of once per year.

Wu et al. (2008) demonstrate the use of a grid-based approach for outlier detection in the South American precipitation data set obtained from the NOAA. Here, the top k outliers are detected and extracted from each of the time periods, and a sequence of outliers are stored using the *Outstretch* algorithm. At the end, all the possible extracted sequences are identified as the spatiotemporal outliers. Despite the large dataset that has been used during the investigation, the running time of the algorithm seems to be admirable.

Rodgers et al. (2009) propose a statistical method to identify spatiotemporal outliers using the *strangeness-based outlier detection* algorithm (*StrOUD*). The “strangeness” measure of each object is the summation of the distances from all its nearest neighbors. Here, the distance between two points are measured as a weighted distance combining their geographical, temporal, and feature vectors distance. By comparing the strangeness factor of an individual object to the baseline strangeness of the normal objects, spatiotemporal outliers can be detected. If the difference is significant, then the object is said to be an outlier.

When focusing purely on spatial outlier detection algorithms, Chen et al. (2008) have proposed a Mahalanobis distance-based approach. Here, the neighborhood of each of

the data points is defined with k nearest neighbor clustering method, using the spatial attributes, such as latitude and longitude. The generated cluster defines the spatial region to which each data point is compared. All nonspatial attributes within the neighborhood will be summarized with the median value. Based on the Mahalanobis distance between the nonspatial attributes of each data point and its difference from the median, individual outliers can be detected. Once the calculated distance becomes too large and exceeds a predefined threshold, the corresponding data point will be treated as an outlier.

Another approach for detecting spatial outliers within a given data set is the *density-based local outlier factor (LOF)* algorithm is proposed by Breunig et al. (2000). Here, the isolation of a data point with respect to its surrounding neighborhood decides its anomaly score. Hence, the samples within the areas of high density are less likely to be anomalous, since they are validated by a large number of similar data samples. Using domain knowledge or further investigations, outliers can be detected based on their assigned local outlier factors.

In general, for the spatiotemporal applications, the purely spatial outlier detection algorithms, applied for each timestamp independently, might not be very suitable, as the temporal correlation needs to be taken care of by the models. The efficiency of the spatiotemporal models highly depends on the resolutions (spatial and temporal) of the application dataset, their autocorrelation, measurement uncertainty, etc. In some cases, adding additional context of the study region to the process may help to define an outlier more accurately.

Summary or Conclusions

Spatiotemporal dataset has three components in general, *attributes*, *space*, and *time*. Modeling approaches of spatiotemporal data have covered a broad spectrum of applications in many fields, including environmental applications, crime hotspot analysis, healthcare informatics, transportation modeling, social media, and many others. Clustering, predictive learning, frequent pattern mining, anomaly detection, change detection, and relationship mining are the few broad categories of the modeling approaches irrespective of the applications (Atluri et al. 2018). This chapter discusses some modeling approaches used for environmental applications in general. Further, one spatiotemporal modeling approach of outlier detection is chosen and presented here. Outlier detection within the application data is an essential preprocessing step for most of the spatiotemporal applications. Some important literature on spatiotemporal outlier detection methods is also discussed. Though the applications and methods presented here are not exhaustive, this chapter

gives the initial pointers for further exploration of the spatio-temporal models.

Definition

Spatiotemporal weighted regression (STWR) (Que et al. 2020) is a new time dimension extended GWR-based model for analyzing local nonstationarity in space and time. Different from geographically and temporally weighted regression (GTWR) (Huang et al. 2010; Fotheringham et al. 2015), a novel concept of time distance, which is the rate of value difference between regression and observed points rather than the time interval, is proposed for weighting the local temporal effects. STWR utilizes a new designed weighted average form of spatiotemporal kernel for combining the spatial weights and temporal weights.

Introduction

Geographically weighted regression (GWR) (Brunsdon et al. 1996; Fotheringham et al. 2003) is a useful tool for exploring the potential spatial heterogeneity in geospatial processes. It is

widely applied in many geoscience-related fields, such as climate science (Brown et al. 2012), geology (Atkinson et al. 2003), and environmental science (Mennis and Jordan 2005).

In addition to spatial heterogeneity, temporal heterogeneity also exists widely in the natural and geospatial process. Although the geographically and temporally weighted regression (GTWR) (Huang et al. 2010) can incorporate the time dimension into GWR model, the fitting and prediction performances of GTWR usually do not outperform the basic GWR model. It is probably because of the design and configuration of the spatiotemporal kernel, which might limit the performance of spatiotemporal weight matrix in GTWR.

The GTWR model (Huang et al. 2010) takes time as a new distance dimension, combining with the spatial dimension to calculate the spatiotemporal (Euclidean) distance, and then obtains the weight through the Gaussian or bi-square kernel. However, time and space are at different scales and dimensions, and their units, scales, and impacts on regression points are fundamentally different. Although GTWR uses the adjustment factor τ to synthesize the distance between time and space, directly integrating the spatial distance and time distance is easily misleading (Fotheringham et al. 2015), and the performances of fitting and prediction are sometimes inferior to traditional GWR models. A GTWR (Fotheringham et al. 2015) model uses a set of time-isolated spatial bandwidths to calculate the weights of the influence of observation points on regression points in space and time. But the calibration process is cumbersome and cannot simultaneously optimize time and space bandwidth.

Both GTWR models use the time interval as the time distance, and they use the distance decay kernel function to calculate the weight. It will cause the observation points of different spatial positions recorded at the same time in the past to have the same temporal impacts on the regression point. However, at these observed points, some values change significantly, while others may be almost unchanged. The magnitude of the value change has a different influence on the regression point. The more significant the value change during the time interval, the higher the impact it is. The rate of change of attribute values (nonstationarity in time) also has heterogeneity in spatial position. Using the time interval as the time distance to calculate the weight cannot fully capture the local spatiotemporal effects from observations to the regression point.

Besides, the spatiotemporal kernel of both GTWR models takes the form of multiplying the time kernel and the space kernel function (whose value range of the kernel function is 0–1). However, the multiple forms may cause the problem of time and space interaction, supposing the temporal weight and the spatial weight of an observation point on the regression point is equal to 0.9, while the temporal weight to 0.1. If multiple forms are adopted, the weight value of the

observation point on the regression point will eventually change by 0.09. The weight value might be improper for the spatiotemporal effects. Supposed a house B (observation point) is very close to a house A (regression point) in space. And the house price of B is observed in a relatively long-time interval from now (not exceeding the optimized temporal bandwidth). The multiplying weight values may not correctly reflect the spatiotemporal effect of the observation house price at B on the current house price at the regression point A. If the rates of house prices near A change fast, the past price of B will still have substantial impacts on the current price at A. But if adopted the time interval as the time distance, the composited weight value will be seriously underestimated. How to establish a spatiotemporal kernel to capture the actual weights of observation points to the current regression points becomes a problem worthy study.

Unlike both geographical and temporal weighted regression (GTWR) (Huang et al. 2010; Fotheringham et al. 2015) mentioned above, STWR (Que et al. 2020) proposed a novel time-distance decay weighting method, in which the time distance is the rate of value difference through a time interval rather than the time interval between an observed point and a regression point. Based on the temporal weighting method (temporal kernel), the degree of temporal impact from each observed point to a regression point can be measured, which is a highlighted feature in STWR. Besides, a weighted average form of the spatiotemporal kernel, instead of multiplication form in GTWR (Huang et al. 2010; Fotheringham et al. 2015), was proposed in STWR, which can better capture the combined effects of a nonstationary spatiotemporal process from observed data than GTWR.

These characteristics enable STWR to significantly outperform the GWR and GTWR in model fitting and prediction for the latest observed time stage. Thus, STWR is a practical tool for analyzing the local nonstationary in spatiotemporal process.

Model Formulation

Principle of GWR

GWR is the background of STWR; it is helpful to introduce the basic framework of GWR (Brunsdon et al. 1996; Fotheringham et al. 1996, 2003). The basic formulation of GWR is described in Eq. 1:

$$y_i = \beta_0(u_i, v_i) + \sum_k \beta_k(u_i, v_i)x_{ik} + \varepsilon_i \quad (1)$$

In Eq. 1, (u_i, v_i) is the coordinate of a point i , and y_i is a response variable of the point i . x_{ik} is the k^{th} dependent variable, and ε_i denotes the error term, which is assumed to be independent and drawn identically from the normal

Spatiotemporal Weighted Regression, Fig. 1 Spatiotemporal impacts of observed points with different rates of value change on a regression point at time stage T. Temporal bandwidth is the length of

time from the intersection point A of the spatiotemporal bandwidth and the timeline to the regression point. Spatial bandwidth and spatiotemporal bandwidth are illustrated in the figure legend (Que et al. 2020)

distribution $N(0, \sigma^2)$, i.e., i.i.d. The main difference between GWR and the general global regression method, such as ordinary least squares (OLS), is that GWR allows the coefficient $\beta_k(u_i, v_i)$ vary spatially to identify spatial heterogeneity. The estimated coefficient $\hat{\beta}_k(u_i, v_i)$ can be expressed by Eq. 2:

$$\hat{\beta}_k(u_i, v_i) = (X^T W(u_i, v_i) X)^{-1} X^T W(u_i, v_i) y \quad (2)$$

In Eq. 2, $W(u_i, v_i)$ denotes a diagonal matrix, whose diagonal elements represent the influence of each observation point on the regression point i . The weight values of the diagonal elements are obtained by the bi-square or Gaussian kernel function with inputting their distances. An optimal spatial bandwidth can be optimized through minimizing the errors of the regression model.

After introducing the time dimension, to calibrate the regression point, the model not only needs to “borrow points” from the nearby spatial location but also “borrow points” from the near past time to capture local spatial and temporal effects. To obtain the weight matrix $W(u_i, v_i)$, we need a spatiotemporal kernel and to optimize the temporal bandwidth and spatial bandwidth.

Time-Distance Decay Weighting Strategy Based on the Rate of Value Difference between Regression and Observed Points

Like the spatial distance decay weighting strategy, the time-distance decay weighting strategy is discussed in the previous GTWR model (Crespo et al. 2007; Huang et al. 2010; Wu et al. 2014; Fotheringham et al. 2015). Supposed T-s, T-q, T-p,

and T are the four-time stages from the past to present (Fig. 1). STWR considers the effects of rate of value difference between different observation points and the regression point. Although some data points are farther away from the regression point in space, they may have more significant influences on the regression point (because of the different temporal effects among observed points). As shown at the T-p time stage in Fig. 1, some star points are farther from the regression point in space than some pentagonal points. STWR can better capture the mixed effects of time and space. If the time of the observation point is too old or the rate of numerical difference is too low, that is, exceeding the time-bandwidth, then the weight of temporal effects from the observation point to the regression point is 0.

Spatiotemporal Kernel

Suppose a set of observation points $O_{\Delta t} = \{O_{N_t}, O_{N_{t-1}}, \dots, O_{N_{t-q}} | \Delta t = [t-q, t]\}$ is collected within a certain time interval Δt , where t denotes the current time stage and $N_t - i, i \in \{0, 1, 2, \dots, q\} (N_t = N_t - 0)$ is the number of points observed at each time stage. In STWR, the spatiotemporal takes the weighted average form:

$$w_{ijST}^t = (1 - \alpha)k_s(d_{sij}, b_{ST}) + \alpha k_T(d_{tij}, b_T), 0 \leq \alpha \leq 1 \quad (3)$$

In Eq. 3, w_{ijST}^t denotes the spatiotemporal weight on the observed location j at time stage t . k_s and k_T , both ranging from 0 to 1, are the spatial and temporal kernel, respectively. α is an

adjustable parameter used to weigh the strength of effects from local time and space. It can be optimized by using the same search strategy as bandwidth optimization. b_{ST} is the spatial bandwidth b_S at a certain time stage T , and b_T denotes

the temporal bandwidth. d_{sij} and d_{tij} denote the spatial (Euclidean) and temporal distance between the regression point i and an observed data point j , respectively. In STWR, the temporal kernel k_T is specified as below:

$$w'_{ijST} = \begin{cases} \left[\frac{2}{1 + \exp\left(-\frac{|(y_{i(t)} - y_{j(t-q)})/y_{j(t-q)}|}{\Delta t/b_T}\right)} - 1 \right], & \text{if } 0 < \Delta t < b_T \\ 0, & \text{otherwise} \end{cases} \quad (4)$$

In Eq. 4, Δt is the time interval. $y_{i(t)} - y_{j(t-q)}$ denotes the value difference between the observed value of regression point i at t and the value of observation point j at $t - q$. The weight will be set to zero if the time interval Δt is out of the range $(0, b_T)$. Compared with GTWR models, the temporal kernel k_T of STWR can better capture the effects of temporal variation. Thus, it can represent that the faster the rate of value difference is during a certain time interval (within the temporal bandwidth), the bigger weight value it will be.

In the spatiotemporal process context, the optimized spatial bandwidth can also vary over time. Various functions can be specified for describing the variation of spatial bandwidth

over time. For convenience of model calibration, STWR assumed that the relationship is linear:

$$b_{ST} = b_{St} - \tan\theta * \Delta t, \quad -\frac{\pi}{2} < \theta < \frac{\pi}{2} \quad (5)$$

In Eq. 5, $\tan\theta$ denotes the slope of the spatial bandwidth change with time Δt . Combining with spatial kernel k_s , such as the bi-square kernel and Gaussian kernel (Fotheringham et al. 2003), and then substituting them into Eq. 3, two corresponding spatiotemporal kernel functions can be drawn:

$$w'_{ijST} = \begin{cases} \left[(1 - \alpha) * \left[1 - \left(\frac{d_{sij}}{b_{St} - \tan\theta * \Delta t} \right)^2 \right]^2 + \alpha * \left(2 / \left(1 + \exp\left(-\frac{|(y_{i(t)} - y_{j(t-q)})/y_{j(t-q)}|}{\Delta t/b_T}\right) \right) - 1 \right) \right], & \text{if } \Delta t < b_T, \text{ and } d_{sij} < (b_{St} - \tan\theta * \Delta t) \\ 0, & \text{otherwise} \end{cases} \quad (6)$$

$$w'_{ijST} = \begin{cases} \left[(1 - \alpha) * \exp\left[-\frac{1}{2} \left(\frac{d_{sij}}{b_{St} - \tan\theta * \Delta t} \right)^2\right] + \alpha * \left(2 / \left(1 + \exp\left(-\frac{|(y_{i(t)} - y_{j(t-q)})/y_{j(t-q)}|}{\Delta t/b_T}\right) \right) - 1 \right) \right], & \text{if } \Delta t < b_T, \text{ and } d_{sij} < (b_{St} - \tan\theta * \Delta t) \\ 0, & \text{otherwise} \end{cases} \quad (7)$$

Equations 8 and 9 are based on the bi-square and Gaussian spatial kernel, respectively. b_{St} is the initial spatial bandwidth at the given time stage t of the regression point (i.e., t is the

initial time for searching observed points in the past). The procedure of optimizing the initial bandwidth is the same as GWR model for observations at t . The STWR model needs to

optimize the parameters α and θ , given the initial spatial bandwidth at t , instead of the spatial bandwidth b_{ST} at every time stages.

Model Calibration

Compared with the general GWR, STWR needs to optimize the parameters α and θ as well as the time stage model used (temporal bandwidth). Some goodness-of-fit diagnostics like the cross-validation (CV) score (Cleveland 1979) or the Akaike information criterion (AIC) (Akaike 1973) and its corrected version AICc (Hurvich et al. 1998) can still be used for the calibration of STWR, whose process is listed below:

1. Sort the input data, and get the total number of observation periods N_t and all observation points O_{N_t} of the latest time stage.
2. Traverse the set of $BT_\lambda = \{\Delta t_1, \Delta t_2, \dots, \Delta t_\lambda\}$ (where Δt_λ denotes the time interval between t and $-\lambda$).
3. Obtain the optimized initial spatial width b_{ST}^* by utilizing the GWR model to fit the latest observation points O_{N_t} .
4. Calculate the limitation of the parameter θ with the range of $[0, \arctan \frac{b_{ST}^*}{\Delta t_\lambda}]$ (ensure the spatial bandwidth b_{ST} at each time stages is greater than 0). And set the limitation of searching spatial bandwidth (the number of the nearest neighbors) with the discrete integer set of $[k + 1, N_t]$.
5. Traverse each element in the set BT_λ and then obtain all observation points for each time interval t_i . Further traverse each possible value within the limitation range in (4).
6. Select a searching strategy, such as the equal interval or the golden section method, to figure out model goodness-of-fit value by trying all parameter α and θ available.
7. Record the model diagnostic value (CV value) with its corresponding model parameter in each step of traversal. When the traversal is completed, find the optimal CV value and its corresponding parameter values.
8. Use the optimal parameters to build the spatiotemporal weight matrix, and then estimate the coefficient $\hat{\beta}(u_i, v_i)$ based on Eq. 2.

Case Study

To test the performance of different models, we designed a study area of 25×25 grids for simulating a five-time stages spatio-temporal process with four different heterogeneous coefficient surfaces (one of which is a constant term). The initial values of the three independent variables were generated by random normal distribution $x_1^{initial} \sim N(110, 25^2)$, $x_2^{initial} \sim N(150, 15^2)$, and $x_3^{initial} \sim N(80, 10^2)$, respectively. Their variance kept unchanged, but mean values varied over time as the Eq. (8). The independent random error is assumed to be drawn from a normal distribution $Err \sim N(0, 30^2)$:

$$x_i^{t+\Delta t} = x_i^t \pm \eta * \Delta t \quad (8)$$

In Eq. 8, η is the parameter to control the rate of variation, and x_i^t denotes the value of the i th independent variable at time t . $x_i^{t+\Delta t}$ is the updated value of x_i^t during a certain time interval Δt .

In this case, we also assumed that the four coefficient surfaces of the constant term and the three independent variables were known, and they were generated by the following Eqs. 9, 10, 11, and 12, respectively.

$$\beta_0 = 3 \quad (9)$$

$$\beta_1 = 1 + 4 * \sin[1/8\pi(u + v)] \quad (10)$$

$$\beta_2 = 1 + \frac{1}{12}(u + v) \quad (11)$$

$$\beta_3 = 1 + \frac{1}{324} [36 - (6 - u/2)^2] [36 - (6 - v/2)^2] \quad (12)$$

We randomly sample 1000 points from the five-time stages described above. Our target is to evaluate the fitting and prediction performances for the last time stage t_4 . Table 1 presents the modeling results of the global OLS, GWR, GTWR, and STWR. STWR utilized observations from all-time stages, the initial spatial bandwidth is 6, and α and θ are 0.04 and 0, respectively. Although the GTWR (Huang et al. 2010) used the observations in the past time stages, its AICc and sum of squared estimate of errors (SSE) are 2721.11 and 7675859.93, which are larger than the basic GWR model of 2714.14 and 2658224.80, respectively. STWR has the highest

Spatiotemporal Weighted Regression,
Table 1 Comparison of model performances

Time stage t_4	AICc	R2	SSE	Sigma
OLS	2866.32	0.07	18634055.73	
GWR	2714.14	0.87	2658224.80	145.88
GTWR	2721.11	0.62	7675859.93	264.79
STWR	2320.09	0.97	565479.53	24.72

Note: the OLS and GWR model only utilized the observation data at t_4 , that is, because they could not process the temporal effects from observations in the past to the regression points at t_4

R-squared (R^2) 0.97, which is greater than GWR of 0.87 and GTWR of 0.62. Besides, both the AICc and SSE of STWR are the lowest of all these models, which indicates that STWR significantly outperforms other models. Also, the estimated standard error (Sigma) of STWR is only 24.72, which is smaller than 145.88 of GWR and 264.79 of GTWR.

In this case, we also tested the prediction performance of the coefficient surfaces by GWR and STWR model (GTWR add-in package of GTWR does not provide prediction functions). Figure 2 shows the results of absolute predicted errors of the regression coefficient surfaces by GWR and STWR. Four absolute predicted errors of estimated coefficient

Spatiotemporal Weighted Regression, Fig. 2 Comparison of the absolute predicted errors of the regression coefficient surfaces between STWR and GWR models, where (e0), (e1), (e2), and (e3) are four absolute predicted errors of estimated coefficient surfaces (corresponding to β_0 , β_1 , β_2 , and β_4) by STWR

(i.e., $|\hat{\beta}_{0_stwr} - \beta_0|$, $|\hat{\beta}_{1_stwr} - \beta_1|$, $|\hat{\beta}_{2_stwr} - \beta_2|$ and $|\hat{\beta}_{3_stwr} - \beta_3|$). (f0), (f1), (f2), and (f3) are four absolute predicted errors of estimated coefficient surfaces by GWR (i.e., $|\hat{\beta}_{0_gwr} - \beta_0|$, $|\hat{\beta}_{1_gwr} - \beta_1|$, $|\hat{\beta}_{2_gwr} - \beta_2|$ and $|\hat{\beta}_{3_gwr} - \beta_3|$)

surfaces by STWR are much smaller than GWR, which indicates that the STWR outperforms GWR in recovering the coefficient surfaces.

Conclusions

Spatiotemporal weighted regression (STWR) is a novel GWR-based model for exploring local nonstationary spatiotemporal processes in nature and socioeconomics. Value change rate is introduced in the temporal kernel which presents significant model fitting and accuracy in our case study. STWR fully incorporates the observed data in past time and outperforms the geographic temporal weighted regression (GTWR) and geographic weighted regression (GWR) models. The temporal bandwidths and the parameter α and θ in the spatiotemporal kernel of STWR can help to analyze the local effects that form space and time. The model may be appropriate for the local spatiotemporal nonstationary processes in more fields.

Spectral Analysis

Katherine L. Silversides

Australian Centre for Field Robotics, Rio Tinto Centre for Mining Automation, The University of Sydney, Sydney, NSW, Australia

Definition

Spectral analysis is a method of transforming sequenced data to extract or filter information. It is frequently used as a preliminary step to simplify further processing. While spectral analysis was initially developed using time series data, it can also be applied to any sequence of data with at least one independent variable. In geoscience this variable is typically distance or depth. The aim is to identify geologically significant short or long term variations from the overall signal. This can be done using either parametric or nonparametric methods.

Introduction

Spectral analysis was initially developed to analyze time-dependent functions and time series, aiming to identify underlying spectral content. This typically involved identifying frequencies within the series that contain significant amplitudes. Nonparametric or parametric methods are applied to a time series, or to any sequential data with at least one independent variable such as spatial coordinates. The analysis separates out spectral content such as waves or oscillations, extracting data or filtering the data to simplify future processing. The signal or data processed by spectral analysis can be either one-dimensional, such as data from a seismograph, or multidimensional, such as seismic reflection surveys (Bath 1974; Buttkus 2000; Jekeli 2017; Stoica and Moses 2005).

Theory

In spectral analysis, the correlation properties of a stationary process $x[n]$ are fully defined by the autocorrelation or Fourier transform, using the power spectral density (PSD). This can be defined as

$$r_x[k] = E[x^*[n]x[n+k]] \leftrightarrow S_x(\omega) = \mathcal{F}\{r_x[k]\}$$

where ω is angular frequency, and $\mathcal{F}$ is the Fourier transform (Spagnolini 2018). As there is only a limited set of N observations, $\mathbf{x} = [x[0], \dots, x[N-1]]^T$, this then becomes:

$$\hat{S}_x(\omega) = \hat{S}_x(\omega|\mathbf{x}).$$

For more complete mathematics, please refer to the Fourier transform and autocorrelation chapters in this book.

Spectral analysis can be applied using either a parametric or non-parametric mathematical model for the PSD. Parametric methods attempt to model the mechanism that generated the data by estimating the correct values of parameters that relate to important characteristics of the physical process. Therefore, information obtained from the model will relate to both the data and the physical processes. Nonparametric methods require no a priori knowledge of the mechanism that generated the data or the correlation between samples. It is a more generic method that has more flexibility (Koopmans 1974; Spagnolini 2018). The method chosen for spectral analysis depends on the type of data to be processed and the desired output, such as defining a cyclical pattern, removing noise, or detecting variations in the data.

Spectral analysis can also be used to filter data, removing noise or unwanted signals to increase the clarity of the desired information. For example, a low-pass filter can be used to remove high frequency data within a signal to remove noise. Other applications produce a high-pass or band-pass filter and the user selects the desired filter depending on the application and the frequency of the useful data that is being extracted (Bath 1974).

Applications

As spectral analysis can be applied to any sequence of data with at least one independent variable, it has a wide range of applications within the geosciences. Three common uses are measuring the seismic moment, seismic reflection surveys, and climate analysis. These are briefly discussed below.

Spectral analysis is often used to investigate the physical properties associated with the sources of natural and induced seismic events (Shemeta and Anderson 2010; Urbancic et al. 1996). Standard magnitude scales for earthquakes (e.g.,

Richter) are empirical and do not provide any information on the physical properties associated with the earthquake. In comparison, the moment magnitude scale is directly related to the slip on the fault and the area of the slip. However, this scale requires the accurate estimate of the seismic moment. While waveform inversion is typically used to estimate the seismic moment for large earthquakes, spectral analysis is frequently used for smaller seismic events. This is typically done using seismogram recording in either the time or frequency domain. In the time domain, the seismic moment can be calculated using the differences in the arrival times of the P- and S-waves, assuming a constant rock density and a known (or calculated) source-receiver distance. This calculation can be affected by the accuracy of the arrival times, the signal to noise ratio, and artifacts in the signal conversion from the seismogram. In the frequency domain, a Fourier transform allows the seismic moment to be directly measured from the amplitude spectra if the low frequencies are sufficiently available. If the low frequencies are not sufficient, a source model spectrum can be fitted to the amplitude spectra instead to estimate the seismic moment (Stork et al. 2014).

Seismic reflection surveys were developed to explore sedimentary basins that have a layered structure and contrasting units. Typically these surveys are used for coal or oil and gas exploration (Taner et al. 1979). The surveys are collected using a seismic source and a series of receivers that collect the signal that is reflected from the subsurface geology. This is done on either a two-dimensional line or a three-dimensional grid and produces a large amount of data that requires both filtering and signal processing. The emitted signal is partially reflected when it encounters geological contacts between two units that have different rock densities and therefore seismic velocities. This may happen multiple times for a single signal, resulting in both a weaker signal and multiple signals received. The time it takes for a signal to reach a receiver depends on both the distance it has travelled and the velocity of the individual rock units. Each individual signal from the receivers needs to be processed using several steps such as filtering, amplitude processing, prestack analysis, deconvolution, and velocity analysis, before the signals can be stacked and processed together. The combined signals are generally filtered using a band-pass method. Most of these steps can be done using spectral analysis and the Fourier transform is commonly used (Gadallah and Fisher 2009).

In climate science, spectral analysis can be used to determine short and long term variations from noisy data. For example, a Fourier transformation into the frequency domain can be used to identify cyclical patterns in a climate system (Mudelsee 2010; Rao and Hsu 2008). This requires estimating the spectral density function and testing for harmonic signals. This typically requires spectral smoothing, and the user must balance the estimation variance and frequency resolution. This could be done using a method such as the

multitaper smoothing method for evenly spaced time series or the Lomb–Scargle method for unevenly spaced data (Mudelsee 2010).

Summary

Spectral analysis uses methods such as the Fourier transform or autocorrelation to analyze time series data and other sequential data with at least one independent variable. The analysis can be used in multiple ways, from extracting waves or oscillations to filtering the data. Parametric methods can be used to obtain information about physical properties, for example, finding the seismic moment from the seismogram record of a small seismic event. Nonparametric methods can be applied more generally, without requiring a priori knowledge. They can be used for filtering and processing signals such as seismic reflections surveys. Therefore, spectral analysis has a wide range of applications to geoscience data and problems.

Spectrum-Area Method

Behnam Sadeghi

EarthByte Group, School of Geosciences, University of Sydney, Sydney, NSW, Australia

Earth and Sustainability Research Centre, University of New South Wales, Sydney, NSW, Australia

Definition

Spectrum-area (S-A) fractal model is a different version of concentration-area (C-A) fractal model, in a frequency domain (Cheng et al. 2000; Zuo and Wang 2016), representing the power-law frequency of the power-spectrum density (Afzal et al. 2013). It also has been introduced as the power-spectrum-volume (P-V) fractal model in 3D (Afzal et al. 2012).

Introduction

Benoit Mandelbrot (1983) introduced fractal geometry as a new branch of nonlinear mathematics. He demonstrated the domination of fractal geometry to Euclidean geometry in modeling the nature (see the entry ► [“Fractal Geometry in Geosciences”](#)). Bölviken et al. (1992) studied the importance of fractal geometry to generate geological models such as geochemical landscapes.

As a significant objective in geochemical exploration, geoscientists always look for the highly anomalous mineralization areas to focus the exploration and mining projects on such areas. To do so, they need to classify the areas and discriminate anomalies from the background areas. This is why, during the last decades, a variety of mathematical and statistical classification models have been developed. For further details, see the entry ► [“Singularity Analysis”](#) and Sadeghi 2020, 2021. Therefore, considering the advantages and disadvantages of the developed models and based on Bölviken et al. (1992), Cheng et al. (1994) proposed the first classification fractal model in a spatial domain, named “concentration-area (C-A) fractal model” – see the entry ► [“Concentration-Area Plot”](#). A few years later, Cheng et al. (2000) demonstrated that geochemical patterns can also be studied in the frequency domain. It means the spatial domain in the C-A model can be taken into consideration as

superimposed signals of a variety of frequencies. Based on this theory, the spectrum-area (S-A) fractal model was introduced. This model discriminates geochemical anomalies from the background by spectral analysis and C-A fractal model applied to the frequency domain. In this entry, after introducing the S-A model in detail, its 3D format, called “power-spectrum-volume (P-V)” (Afzal et al. 2012), will also be discussed.

Spectrum Analysis

Spectrum analysis is a well-developed theory that has been applied in exploration geophysics to discriminate anomalies. For instance, it has been widely applied to detect various frequencies' signals (patterns) representing geological areas and their variety. This theory simply demonstrates a couple of frequency and spatial domains per signal. To convert such signals from spatial domain to frequency domain and vice versa, Fourier and inverse Fourier transformations (FT) are applied, respectively, as follows (Cheng et al. 2000):

$$F(K_x, K_y) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x, y) \cos(K_x x + K_y y) dx dy$$

$$- i \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x, y) \sin(K_x x + K_y y) dx dy$$

$$F(x, y) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} F(K_x, K_y) \cos(K_x x + K_y y) dx dy$$

$$- \frac{i}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} F(K_x, K_y) \sin(K_x x + K_y y) dx dy$$

where K_x and K_y represent wave numbers (WN) per x and y axes; this WN is the frequency spatial equivalent (rad/sec); $f(x, y)$ is the signal in spatial domain.

Methodology: Spectrum-Area (S-A) Fractal Model

The S-A fractal model is a power-law relation between the power spectrum (Fig. 1) of S and the occupied area $A(\geq S)$ (Cheng et al. 2000):

Spectrum-Area Method, Fig. 1 Power-spectrum map generated by FT based on the Swedish till data (from Sadeghi 2020)

$$A(\geq S) \propto S^{-2d/\beta}$$

where S is power spectrum, A represents the area covered by a range of geochemical concentrations, β is an anisotropic scaling exponent, and d is the overall degree of concentration. In other words, $2d$ is associated with elliptical dimension ($d = 1$), which is related to isotropic dimensions.

The S-A model applies FT/inverse FT transformation to convert/convert back of the spatial distribution to the frequency one. The reason why in this model frequency distribution is taken into account is because it highly simplifies some operations such as complex correlation analysis and filtering (Afzal et al. 2013).

Like the C-A model, the S-A model provides a log-log plot but based on the relevant power spectrum and area. To define different geochemical patterns, several straight lines are fit to the log-log plot using least-squares (LS) method – see the entry ► “Concentration-Area Plot” for further details. The straight lines’ cross points are the desired thresholds to discriminate “background,” “noise,” and low/high power-

spectrum values. To define the geochemical anomalies, we need to convert the introduced patterns to the spatial domain (Cheng et al. 2000).

Case Study: Sweden

Based on a till geochemical dataset, collected by the Geological Survey of Sweden (Andersson et al. 2014) (Fig. 2), Sadeghi (2020) developed several novel fractal/multifractal models to separate Cu-related volcanic massive sulfide (VMS) geochemical anomalies through uni-, bi-, and multivariate analyses. Several other traditional fractal/multifractal models, such as C-A and S-A models, were also applied to the same data to compare the results and evaluate their significance. In Fig. 3, the Cu geochemical anomalies, the corresponding FT power-spectrum map, and the S-A log-log plot have been demonstrated. On the log-log plot, two thresholds are defined to filter geochemical background (the first population from left), geochemical anomalies (the middle

line), and noise (the last population in the right hand). Based on the S-A model in Sweden, the main VMS Cu geochemical anomalies are mainly located in NW and Northern Sweden, which are Caledonides and Northern Norrbotten areas.

Power-Spectrum-Volume (P-V) Fractal Model: The 3D Format of S-A Model

The P-V fractal model was developed by Afzal et al. (2012) in 3D to discriminate various mineralization zones in Kahang Cu porphyry deposit in Central Iran, as a case study (Fig. 4):

$$V(\geq S) \propto S^{-2d/\beta}$$

where $V(S)$ denotes the volume occupied by concentrations greater than S . This model is actually based on the relation between power-spectrum values and the volume of the voxels.

Afzal et al. (2012) demonstrated that P-V model is efficient enough to define different mineralization zones. For instance,

in their study, the P-V model successfully recognized supergene and hypogene enrichment zones and differentiated them from the background or the barren host rock (Fig. 4).

Summary and Conclusions

A variety of mathematical and statistical models have been developed to classify geochemical anomalies from the background and identify mineralization zones. Fractal/multifractal models are among the newest and most robust classification models. The C-A fractal model is the first fractal model applied for this sake; then, it was developed in a frequency domain, rather than spatial domain, and introduced as S-A fractal model. This model is based on FT and inverse FT to transform the data from spatial domain to the frequency domain and back. The 3D format of S-A model was introduced later as P-V model, which is also a robust model to characterize mineralization zones in depth.

Splines

Bengt Fornberg
Department of Applied Mathematics, University of Colorado,
Boulder, CO, USA

Definition

A spline is a piecewise polynomial function, commonly used to interpolate or approximate one-dimensional data. At its nodes, it changes from one polynomial to another one, in

such a way that a certain number of derivatives remain continuous. (Typically one derivative less than the degree of the polynomial pieces.)

Introduction

Splines were introduced by Schoenberg in 1946 (Schoenberg 1946). Later generalizations extend to interpolating both gridded and unstructured data in any number of dimensions. General reference books on splines include (de Boor 2001; Dierckx 1993; Powell 1981; Prautzsch et al. 2002).

Interpolation in 1-D, using a single polynomial, is notoriously unstable. Figure 1 contrasts this with piecewise linear and *natural* cubic splines. The first two cases represent extremes, infinitely differentiable but with large oscillations (the Runge phenomenon), vs. not even once differentiable, respectively. Cubic splines provide an attractive compromise. The one shown here minimizes, over every possible interpolating function $s(x)$, the integral $\int s''(x)^2 dx$ over the interval spanned by the outermost nodes. Loosely speaking, it interpolates with the minimal amount of total curvature.

Some Spline Features

For practical use of splines, most coding environments contain a rich set of convenient library routines (including for differentiation, integration, etc.) We therefore focus here on their main concepts, sometimes in simplified cases.

Spline End Conditions

Using between nodes polynomials of degree p (each requiring $p + 1$ coefficients), imposing the function value at each node, and continuity of $p - 1$ derivatives at each interior node is readily seen to leave us short of $p - 1$ pieces of information. We thus need no extra information in the linear ($p = 1$) case (as to be expected for a piecewise linear interpolant), but we are two conditions short in the cubic ($p = 3$) case. Unless specifying otherwise, we focus in the following on this cubic case. Four common options for end conditions are:

1. Set $s'' = 0$ at each end point. This gives the *natural cubic spline*. While of theoretical interest (e.g., minimization of $\int s''(x)^2 dx$, as noted above), the information $s'' = 0$ is typically outright wrong. If nodes are spaced h apart, the error when interpolating a smooth function scales in the interval interior as $O(h^4)$, but the incorrect information reduces this to $O(h^3)$ near to the boundaries.
2. Instead of adding two conditions, one can get the counting right also by taking away two freedoms, such as

Splines, Fig. 1 Contrasting polynomial interpolation with linear and (natural) cubic splines when interpolating the same data. Note different vertical scale in top plot

(a) Single polynomial of minimal degree

(b) First order spline: piecewise linear

(c) Third order (cubic) spline

disallowing a discontinuity in s''' one step in from each boundary – known as *Not-a-Knot*.

3. Fit the slope at each end point with that of the cubic polynomial that interpolates the four points nearest to each end.
4. If one happens to know s' at each boundary, that can be imposed, giving a *clamped spline*.

B-Splines: Concept

Reminiscent of how Lagrange interpolation combines simpler *cardinal* polynomials (one at one node, and zero at the other nodes), it is natural to seek a “simplest” spline, and then represent a general spline as a linear combination of these. A good such choice is the spline that transitions from identical zero non-trivially back to identical zero in the narrowest way possible; cf., Fig. 2 (The customary normalization is that the integral evaluates to one).

B-Splines on Equi-Spaced Nodes

We will mention just three B -spline relations here (in case of unit-spaced nodes and centered at the origin):

1. With $B_p(x)$ denoting the B -spline of order p , and $B_0(x) = \begin{cases} 1 & -\frac{1}{2} < x < \frac{1}{2} \\ 0 & \text{otherwise} \end{cases}$ $B_p(x)$ is the convolution of $B_{p-1}(x)$ with $B_0(x)$.
2. The Fourier transform of a B -spline is remarkably simple: $\int_{-\infty}^{\infty} B_p(x) \cos \omega x dx = \left(\frac{\sin(\omega/2)}{\omega/2} \right)^{p+1}$.
3. Derivatives (and integrals) of B -splines can be conveniently evaluated by using $B'_p(x) = B_{p-1}\left(x + \frac{1}{2}\right) - B_{p-1}\left(x - \frac{1}{2}\right)$.

Creating an Equi-Spaced Cubic Spline Interpolant with the Use of B -Splines

Figure 3 shows schematically (as circles) some data $y(i)$, $i = 0, 1, \dots, N$. Any cubic spline $s(x)$ over these nodes can be written as a linear combination of translates of the cubic B -spline: $s(x) = \sum_{i=-1}^{N+1} \alpha_i B_i(x)$ (the subscript on B now marks the location at which the B -spline is centered, which includes one extra node outside each interval end). The first task is to determine the α_i -coefficients, as the spline then can be readily evaluated at any location. In the linear system (1), the top and

Splines, Fig. 2 Examples of B -splines on unit-spaced grids

Splines, Fig. 3 Schematic illustration of data at $x = 0, 1, 2, \dots, N$ and B -splines centered at $x = -1, 0, 1, 2, \dots, N, N + 1$

bottom equations come from the extra conditions that have to be imposed (shown here for the natural spline), while the remaining equations enforce that the splines takes the correct values at all nodes:

$$\begin{bmatrix} 1 & -2 & 1 & & \\ 1 & 4 & 1 & & \\ & 1 & 4 & 1 & \\ & & \ddots & \ddots & \ddots \\ & & & 1 & 4 & 1 \\ & & & & 1 & -2 & 1 \end{bmatrix} \begin{bmatrix} \alpha_{-1} \\ \alpha_0 \\ \alpha_1 \\ \vdots \\ \alpha_N \\ \alpha_{N+1} \end{bmatrix} = 6 \begin{bmatrix} 0 \\ y_0 \\ y_1 \\ \vdots \\ y_N \\ 0 \end{bmatrix} \quad (1)$$

← Left BC

← Match

← values at

← nodes

← Right BC

The 3-group of entries in the top row (and similarly in the bottom row) are obtained from the fact that $[B_{-1}''(0) \ B_0''(0) \ B_1''(0)] = [1 \ -2 \ 1]$ (making $s'' = 0$). In the case of a Not-a-Knot spline, we similarly need to use that $B'''(x)$ for $x = \{-2, -1, 0, 1, 2\}$ evaluates to $\{1, -2, 0, 2, -1\}$.

Cardinal Splines

Odd order splines are generally preferred over even orders. One reason is illustrated in Fig. 4, where we see spline interpolants to *cardinal data*. In contrast to B -splines, cardinal splines (non-zero at just one node) of degree $p > 1$ oscillate forever. In the cubic case, the amplitudes decay rapidly. (For successive extrema, the ratio of magnitudes approach $2 - \sqrt{3} \approx 0.2679$. Increasing smoothness leads to slower decay; for $p = 5, 7, 9$ the ratios become approximately 0.43, 0.53, 0.61, respectively; approaching 1 as $p \rightarrow \infty$.) In the quadratic spline case, they don't even decay. (This can however be remedied by letting successive quadratics join half-way between where the data values are imposed.) Like with Lagrange's interpolation polynomial, cardinal functions are of more theoretical than computational utility.

Splines on Non-uniformly Spaced Grids

If the nodes are not equi-spaced, the procedure in section [“Creating an Equi-Spaced Cubic Spline Interpolant with the Use of \$B\$ -Splines”](#) still works, as long as we can create non-equispaced cubic B -splines (which will still extend over 5 nodes). There are three main options for finding such:

Splines, Fig. 4 Equi-spaced cardinal splines on an infinite interval

1. Piece-by-piece construction of the cubics.
2. Represent $B(x)$ as a linear combination of the functions $|x - x_k|^3$, $k = 1, 2, \dots, 5$.
3. Use recursions similar to those in Newton's interpolation formula (detailed for ex. in (de Boor 2001), Chapter X and (Powell 1981), Section 19.4).

For **Case (1)**, one notes that, at a node $x = x_i$, the two cubics that meet can only differ by a term $\alpha_i(x - x_i)^3$. After 5 nodes, the requirement of starting and ending with all 4 cubic polynomial coefficients zero leads to a 4×5 homogeneous linear system, guaranteed to have a nontrivial solution.

For **Case (2)**, with equi-spaced nodes at $x = \{-2, -1, 0, 1, 2\}$,

$$B(x) = \frac{1}{12} \left(|x+2|^3 - 4|x+1|^3 + 6|x|^3 - 4|x-1|^3 + |x-2|^3 \right) \quad (2)$$

This function satisfies all the requirements of a B -spline: It is a cubic in each sub-interval, jumps only the third derivative at the nodes, and becomes identically zero outside $[-2, 2]$. This formula generalizes to arbitrarily spaced nodes:

$$B(x) = 2 \left(\frac{|x-x_1|^3}{\prod_{k \neq 1} (x_1 - x_k)} + \frac{|x-x_2|^3}{\prod_{k \neq 2} (x_2 - x_k)} + \dots + \frac{|x-x_5|^3}{\prod_{k \neq 5} (x_5 - x_k)} \right), \quad (3)$$

(again normalized to make the integral equal to one).

Some Generalizations

Parametric Splines

A curve in d dimensions, given by points $x_1(i), x_2(i), \dots, x_d(i)$, $i = 0, 1, \dots, N$, can be interpolated by equi-spaced splines in the joint parameter i .

Smoothing Splines

Given many points, maybe with noise present, interpolation might cause over-fitting. On a unit spaced grid, a very simplistic approach is to use as B -spline coefficients directly the function values (instead of calculating these for ex. by (1)).

In the *Modified Akima* approach (Akima 1970), the pieces are still cubics, but give up the continuity of second derivative at nodes in exchange for much reduced oscillations. This approach can be advantageous, e.g., when dealing with variables that ought not change sign (such as pressure, density, etc.).

Least Square Fitting with Splines

The advantage over smoothing splines is that one can utilize that smoother curves need fewer coefficients. If one wishes to write an own implementation, one can form an over-determined linear system $A\mathbf{a} = \mathbf{y}$, where $\mathbf{a}$ will provide the B -spline coefficients of the resulting spline. The vector $\mathbf{y}$ should be the full set of data values, and the columns of A should be made up of the different B -splines, when evaluated at the respective data locations. This matrix A will be sparse, so iterative solvers will be attractive for very large problem sizes.

Generalizations to Multiple Dimensions

Structured Nodes in Multiple Dimensions

Bicubic splines on 2-D rectilinear grids were introduced in (de Boor 1962). Higher dimensional counterparts to the 1-D B -spline are then obtained by forming tensor products, as illustrated in the 2-D case in Fig. 5. Linear combinations of such can then be used similarly to the 1-D illustration in Fig. 3.

Splines, Fig. 5 Tensor product of cubic B -splines in 2-D

Unstructured Nodes in Multiple Dimensions: Radial Basis Functions (RBFs)

The following two observations lead to major opportunities for generalizing splines:

1. The interpolation accuracy of splines of order p on a grid with spacing h scales as $O(h^{p+1})$.
2. A 1-D function $s(x) = \sum_{k=1}^N \lambda_k |x - x_k|^p$ is a spline of order p (assuming p odd (If p is even, this formula instead gives a single polynomial of degree p .); cf. (2), (3)).

This can be written as

$$s(x) = \sum_{k=1}^N \lambda_k \phi(|x - x_k|), \text{ with } \phi(r) = r^p. \quad (4)$$

Regarding item #1, the order of the error $O(h^{p+1})$ is a consequence of $|r|^p$ (with p odd) having its p^{th} derivative discontinuous at the origin. Choosing instead, say, $\phi(r) = e^{-(\varepsilon r)^2}$ (where $\varepsilon > 0$ is a *shape parameter*), there is no derivative discontinuity, and the accuracy generally improves from algebraic to spectral (beyond any algebraic order).

Regarding item #2, one can generalize (4) to

$$s(\underline{x}) = \sum_{k=1}^N \lambda_k \phi(\|\underline{x} - \underline{x}_k\|), \quad (5)$$

where $\|\cdot\|$ denotes the standard Euclidean 2-norm. Here, the nodes $\underline{x}_k$ can be arbitrarily scattered in a d -dimensional space. For a wide choice of radial functions $\phi(r)$, the linear system for the $\underline{\lambda}_k$ that arises when enforcing $s(\underline{x}_k) = \underline{y}_k$ (function values at the nodes) can never be singular, no matter how distinct nodes $\underline{x}_k$, $k = 1, 2, \dots, N$ are scattered in any number of dimensions.

A wealth of theory and practical computational results and enhancements are available, such as

1. Using $\phi(r) = r^2 \log r$ and $\phi(r) = r$ generalizes to 2-D and 3-D, respectively, the cubic spline minimal curvature result.
2. As described above, the linear systems will have a full (rather than a sparse) coefficient matrix. However, the “local” RBF-FD (Radial Basis Function-generated Finite Differences) approach overcomes this. (RBF-FD for interpolation is closely related to *kriging* – a statistically motivated approach to also predict function values by weighted average of nearby known ones. Splines and kriging are compared in (Dubrule 1984).)
3. With RBF-FD, it can be advantageous to use $\phi(r) = r^3$ and $\phi(r) = r^5$ (as for cubic and quintic splines), but to supplement the RBF sum with multivariate polynomials.
4. Applications of RBF-FD extend well beyond data interpolation, to solving a wide range of PDEs in complex geometries.

RBFs in the present application of geoscience are surveyed in (Flyer et al. 2014; Fornberg and Flyer 2015).

Summary and Conclusions

Splines provide a routine approach for interpolating or for finding smooth approximations to data, especially in one dimension. A rich set of library routines are available in almost all programming environments. Available variations include reduction of data noise, adjusting smoothness, and preventing spurious oscillations (such as enforcing positivity), etc. Generalizations are also available both to gridded and to fully unstructured data in higher dimensions.

Standard Deviation

Alejandro C. Frery

School of Mathematics and Statistics, Victoria University of Wellington, Wellington, New Zealand

Definition

The standard deviation is a measure of spread of either a random variable or a sample. When referring to a random variable, it requires the existence of at least the second moment. When referring to a sample, it requires at least two observations.

Overview

Consider the real-valued random variable $X: \Omega \rightarrow \mathbb{R}$, in which Ω is the sample space; the distribution of X is uniquely characterized by its cumulative distribution function $F_X(t) = \Pr(X \leq t)$. Moreover, if X is continuous, then its distribution is also characterized by the probability density function $f_X(x) = dF_X(x)/dx$. The first and second moments of the continuous random variable X are, respectively, $E(X) = \int xf(x)dx$ and $E(X^2) = \int x^2f(x)dx$, provided the integrals exist. If X is discrete with values in $\Xi = \{\xi_1, \xi_2, \dots\} \subset \mathbb{R}$, the distribution of X is uniquely characterized by the probability function $p_X = (\xi_i, p_i = \Pr(X = \xi_i))$. The first and second moments of the discrete random variable X are, respectively, $E(X) = \sum_i \xi_i p_i$ and $E(X^2) = \sum_i \xi_i^2 p_i$, provided the sums exist. If both $E(X)$ and $E(X^2)$ are finite, then the variance of X is also finite and is given by $\text{Var}(X) = \sigma^2(X) = E(X^2) - (E(X))^2$. We then define the standard deviation of X as the square root of its

variance: $\text{SD}(X) = \sigma(X) = \sqrt{\text{Var}(X)}$. Since the variance cannot be negative, this quantity is always well defined.

The standard deviation is a measure of the spread of the distribution around its expected value. It is expressed in the same units of the random variable. Table 1 presents the name, notation, probability density function, and standard deviation of some commonly used continuous distributions. We denote the indicator function of the set A as $\mathbb{1}_A(x)$, i.e., $\mathbb{1}_A(x)$ is one if $x \in A$ and zero otherwise. The gamma function $\Gamma(z)$ is the extension of the factorial function to complex and, in our case, real numbers: $\Gamma(z) = \int_{\mathbb{R}_+} x^{z-1} e^{-x} dx$. Notice that the gamma distribution reduces to the exponential distribution when $\alpha = 1$. Also, the Student's t-distribution becomes the Cauchy distribution when $\nu = 1$ (Fig. 1).

Table 2 presents the name, notation, parameter space, probability function, and standard deviation of some commonly used discrete distributions.

Figure 2 shows the probability function of a Poisson random variable with mean $\lambda = 3.5$, along with the mean and the area corresponding to $\lambda \pm \sqrt{\lambda}$. The probability in this area is $\Pr(2 \leq X \leq 5) \approx 0.72$.

The Chebyshev's inequality relates the mean and standard deviation of a random variable with the probability of observing values distant from the mean:

$$\Pr(|X - \mu| \geq z\sigma) \leq \frac{1}{z^2}.$$

Consider the sample n of real values $\mathbf{x} = (x_1, x_2, \dots, x_n)$. The sample mean is $\bar{\mathbf{x}} = n^{-1} \sum_{i=1}^n x_i$, and the sample standard deviation is $s(\mathbf{x}) = \sqrt{n^{-1} \sum_{i=1}^n (x_i - \bar{\mathbf{x}})^2}$.

The user should always check the accuracy of the computational platform. Simple computations as, for instance, the sample standard deviation, are prone to gross numerical errors. The reader is referred to the work by Almiron et al. (2010) for an analysis of the numerical precision of five

Stationarity

Francky Fouedjio
Department of Geological Sciences, Stanford University,
Stanford, CA, USA

Definition

The stationarity concept refers to the translation invariance of all or some statistical characteristics of a random function (also referred to as random field or spatial stochastic process). A random function is called strictly stationary if its spatial distribution is invariant under spatial shifts. Second-order (or weakly or wide-sense) stationarity for a random function means that its first- and second-order moments are translation invariant. A random function is said to be intrinsically stationary if its increments are second-order (or weakly or wide-sense) stationary random functions. A random function is said to be locally (or quasi) second-order stationary if its first two moments are approximately stationary at any given position of a neighborhood moved around in the study domain.

Introduction

A classical problem in geosciences is predicting a spatially continuous variable of interest over the whole study region, from measurements taken at some locations. Examples of spatially continuous variables include the elevation, the temperature, the moisture, the rainfall, the soil fertility, the permeability, the porosity, and the mineral grade. In geostatistics, the spatially continuous variable of interest is modeled as a random function (also referred to as random field or spatial stochastic process) and the observed data as the random function's unique realization. Simplifying modeling assumptions such as the stationarity are often made on the random function to make the statistical inference possible. The notion of stationarity broadly refers to the invariance by translation of all or part of the random function's spatial distribution.

The need for a stationarity assumption is based on the fact that any type of statistical inference requires some sort of data replication. Two reasons prevent us from carrying out statistical inference in all generality. On the one hand, one has only a single realization of the random function; the observed data are considered as a unique realization of the random function. This takes all its meaning because there are not multiple parallel physical worlds. On the other hand, the realization is only partially known at certain sampling locations. However, this second restriction is not as problematic as the first one. The question of inference would still arise if one knew the reality exhaustively because the spatial distribution or its moments are not regional quantities (i.e., any quantity whose value is determined by the data). To evaluate them, it would take many realizations (multiple copies) of the random function, but these are purely theoretical and do not exist in reality.

To get out of this impasse, certain restrictions on the random function are necessary. They appeal to the notion of stationarity, which describes, in a way, a form of spatial homogeneity of the random function. The basic idea is to allow statistical inference by replacing the replication on the realizations of the random function by the replication in the space. Thus, the values encountered in the different areas of the study region present the same characteristics and can be considered as different realizations of the same random function. Thus, the stationarity assumption provides some replication of the data, which makes statistical inference possible.
